Approximately 2.3 million people worldwide have MS. Diagnosis usually occurs between 20 and 50 years, affecting twice as many women as men. Whites and people of northern European heritage are more likely to develop MS; prevalence decreases with decrease in latitude. Risk factors include family history of MS, autoimmune diseases, or migraine; personal history of autoimmune diseases or migraine; and, in women, cigarette smoke exposure.

Etiology

- Inheritance Theory

Family members of MS patients have a 5% risk; monozygotic twins have a concordance rate of 25% to 30%. Genetics cannot fully explain the etiology of MS because only a small proportion of patients report a family member with MS; however, genetic risks may explain up to 35% of cases.

- Environment Theory

Epstein-Barr virus is thought to be a possible infectious etiologic agent. Infection cannot fully explain MS because there is a high rate of seropositivity in the population, but MS is much less common. Other environmental theories involve decreased patient or maternal vitamin D serum concentrations or high sodium consumption.

PATHOPHYSIOLOGY

While the causative agent of MS is unclear, the result is the development of an autoimmune disorder with areas of CNS inflammation and degeneration.

Inflammation

An unknown antigen presented by the major histocompatibility complex (MHC) class II molecules causes T-cells to become autoreactive (Figure 30–1). Autoreactive T-cells enter lymphatic tissues to expand. Upon a signal involving sphingosine-1-phosphate, T-cells reenter the circulation. Once activated, T-cells attach to upregulated adhesion molecules and produce matrix metalloproteinases (MMP) that cause blood–brain barrier breakdown. In the CNS, T-cells come into contact with antigen-presenting cells and proliferate. The T-helper cells differentiate into proinflammatory T-helper-1 cells (Th1 cells) and anti-inflammatory T-helper-2 cells (Th2 cells). Th1 cells secrete cytokines that enhance macrophage and microglial cells that attack myelin. B-cells cross damaged sections of the blood–brain barrier where autoreactive T-cells trigger B-cells to form myelin autoantibodies. B-cell antibodies also initiate the complement cascade, causing myelin degradation. These inflammatory processes probably cause relapses. All current MS therapies are targeted toward preventing or slowing the inflammatory processes.

Degeneration

Axonal injury and transection disrupts nerve signals. Growing evidence suggests cytotoxic T-cells cause axonal injury as early as 2 weeks after diagnosis and throughout the disease. Axonal loss is likely responsible for MS progression.

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Course

- Key Concept: MS is classified into relapsing and progressive disease (Figure 30–2). These categories are subclassified according to disease activity and progression. Clinically isolated syndrome (CIS) is a first clinical presentation for which the criteria of dissemination in time has not been met to diagnose MS.

Relapsing-remitting MS is the most common form (85%), developing into progressive form in 50% of patients within...
Autoimmune theory of the pathogenesis of MS. In MS, the immunogenic cells tend to be more myelin-reactive, and these T-cells produce cytokines mimicking a Th1-mediated proinflammatory reaction. T-helper cells (CD4+) appear to be key initiators of myelin destruction in MS. These autoreactive CD4+ cells, especially of the Th1 subtype, are activated in the periphery, perhaps following a viral infection. The activation of T- and B-cells requires two signals. The first signal is the interaction between MHC and antigen presenting cell (APC) (macrophage, dendritic cell, B-cell). The second signal consists of the binding between B7 on the APC and CD40L expressed on T-cells interaction to signal the proliferation of B-cells within the blood-brain barrier following the entry of T-cells. The T-cells in the periphery express adhesion molecules on their surfaces that allow them to attach and roll along the endothelial cells that constitute the blood-brain barrier. The activated T-cells also produce MMP that help to create openings in the blood–brain barrier, allowing entry of the activated T-cells past the blood–brain barrier and into the CNS. Once inside the CNS, the T cells produce proinflammatory cytokines, especially interleukins (ILs) 1, 2, 12, 17, and 23, tumor necrosis factor-α (TNF-α), and interferon-γ (IFN-γ), which further create openings in the blood–brain barrier, allowing entry of B-cells, complement, macrophages, and antibodies. The T-cells also interact within the CNS with the resident microglia, astrocytes, and macrophages, further enhancing production of proinflammatory cytokines and other potential mediators of CNS damage, including reactive oxygen intermediates and nitric oxide. The role of modulating, or downregulating, cytokines such as IL-4, IL-5, IL-10, and transforming growth factor-β (TGF-β) also has been described. These cytokines are the products of CD4+, CD8+, and Th1-cells. New pathogenic mechanisms involve, but are not limited to, receptor-ligand-mediated T-cell entry via choroid plexus (CCR6-CCL20 axis), coupling of key receptor-ligands for inhibition of myelination/demyelination (LINGO-1/NOGO66/p75, or TROY complex, Jagged-Notch signaling). (AG, antigens; APC, antigen-presenting cell; DC, dendritic cell; IgG, immunoglobulin G; Mφ, macrophage; Na+, sodium ion; MMP, matrix metalloproteinases; MHC, major histocompatibility complex; OPC, oligodendrocyte precursor cell; VLA, very late antigen; VCAM, vascular cell adhesion molecule.) (From Bainbridge JL, Miravalle A, Corboy JR. Multiple sclerosis. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach. 9th ed. New York, NY: McGraw-Hill; 2014:835–854, with permission.)
### Clinical Presentation of MS

MS symptoms depend on the location of lesions within the CNS. Myelin increases the speed of nerve impulse transmission; demyelination slows the speed. No impulses can be transmitted if the axon is transected. The primary symptoms of MS are caused by this delay or cessation of impulses. Secondary symptoms of MS result from the primary symptoms.

**FIGURE 30–2.** Clinical Patterns of Multiple Sclerosis.\(^a\) Clinically isolated syndrome, if active, may fulfill multiple sclerosis diagnostic criteria. \(^b\) Progressive disease may be primary progressive with progressive accumulation of disability from onset or secondary progressive with progressive accumulation of disability after initial relapsing course.
10 years. MS reduces life expectancy by 10 to 12 years. Suicide is high in MS patients, 7.5 times the rate of healthy controls.

**Diagnosis**

Relapsing MS diagnosis requires plaque dissemination in time and space. Using the clinical examination with magnetic resonance imaging (MRI) data facilitates earlier diagnosis and treatment (Figure 30–3). Progressive MS diagnosis requires 1 year of disease progression and two of the following: dissemination in space on MRI of the brain, dissemination in space on MRI in the spinal cord based on two or more T2-weighted lesions, and positive cerebrospinal fluid (CSF) (oligoclonal immunoglobulin G bands or elevated immunoglobulin G index).

**TREATMENT**

**Desired Outcomes and General Approach to Treatment**

The goal of treatment is preventing permanent neurologic damage. There are three approaches to treatment.

1. **First**, treat acute relapses with corticosteroids to speed recovery.  
2. **Second**, disease-modifying therapies decrease the number of relapses, prevent permanent neurologic damage, and prevent disability.  
3. **Third**, symptomatic treatments minimize quality of life impact of MS.

**Pharmacologic Treatment**

- **Treatment of Acute Relapses with Corticosteroids**

  **Pharmacology and Mechanism of Action** The mechanism of action of corticosteroids may involve:
  - Prevention of inflammatory cytokine activation
  - Inhibition of T- and B-cell activation
  - Prevention of immune cells from entering the CNS

  Corticosteroids hasten functional recovery. Equal efficacy of equivalent doses of IV and oral dosage forms has been shown with oral dosing avoiding discomfort, inconvenience, and expense of IV therapy.

  **Adverse Effects** The most common adverse effects are gastrointestinal upset, insomnia, and mood disturbance.

  **Dosing and Administration** Methylprednisolone is given 500 to 1000 mg/day IV as one dose or in divided doses. Oral prednisone 1250 mg/day or oral methylprednisolone 1000 to 1250 mg/day provides an equivalent dose. These regimens are given for 3 to 7 days.

  Clinical improvement usually begins during treatment. Recovery is equivalent with or without a subsequent oral corticosteroid taper.

- **Outcome Evaluation**
  - Monitor for symptom improvement
  - Educate regarding adverse effects
Disease-Modifying Therapies

Agents indicated for MS are shown in Table 30–1. These immunomodulators reduce annualized relapse rates 30% to 70%,12–25 No agents are approved for primary progressive MS; however, the available disease-modifying therapies may be effective in patients with progressive disease who have relapses.

- **β-Interferons**

**Pharmacology and Mechanism of Action** The following mechanisms of action are thought to be important:
- Decrease in T-cell activation, decreasing cytokine secretion
- Prevention of upregulation of adhesion molecules on activated T-cells, limiting T-cells access to the CNS
- Suppression of MMPs, maintaining the integrity of the blood–brain barrier
- Decrease in microglial proliferation, preserving myelin
- Promotion of formation of Th2 cells rather than Th1 cells, decreasing inflammation
- Increase in neural growth factor production, assisting in repair of the CNS12,26

**Efficacy in Patients with Relapsing Remitting MS**

β-Interferons reduce relapses by about one-third versus placebo.12 CIS treatment resulted in fewer patients developing clinically definite MS compared with placebo.12

**Efficacy in Patients with Secondary Progressive MS Who Experience Relapses** β-Interferons reduce the risk of relapses, but do not slow progression.13 Treatment is most effective if clinical relapses or MRI inflammatory activity is present.13

**Adverse Effects** Adverse effects are common with β-interferons (Tables 30–1 and 30–2). Flu-like symptoms (fever, fatigue, muscle aches, malaise, and chills) begin a few hours postinjection and dissipate within 8 to 24 hours.14 Injection site reactions range from redness to necrosis. There are preventive and treatment measures for these reactions (Table 30–3). Because of conflicting data, it is difficult to determine if β-interferons cause depression.15

**Tests for Responsiveness** Some patients do not respond to β-interferons; it may be possible to identify nonresponders by determining the type I interferon signature. Patients who have increased expression of the type I interferon gene (interferonα) have more proinflammatory effects. Interferonα patients are less likely to respond to β-interferons than interferonβ patients.26 Antibodies to β-interferons can reduce effect.12 Neutralizing antibodies develop 6 to 18 months after initiation. Neutralizing antibodies can form against any β-interferon and are cross-reactive.12 Neutralizing antibodies may disappear even during continued treatment. There are no standardized recommendations for neutralizing antibody testing.12

- **Glatiramer Acetate**

**Pharmacology and Mechanism of Action** Glatiramer acetate’s mechanism of action is unknown; the following properties are observed:
- Binds to MHC class II, blocking the activation of T-cells
- Activates Th2 cells, preventing inflammation
- Activated Th2 cells secrete brain-derived neurotrophic factor, which may be neuroprotective17

**Efficacy** Glatiramer acetate reduces relapses by 28% compared with placebo, but does not prevent sustained progression of MS.18 It is used in CIS to prevent conversion to clinically definite MS.17

**Adverse Effects** Patients report injection site reactions (see Table 30–2). Icing the injection site preinjection and postinjection and/or topical anesthetics improve these reactions. If a systemic reaction (flushing, chest tightness, palpitations, anxiety, and shortness of breath) occurs, it is usually within 30 minutes of the injection; recurrence is infrequent. Doses may be reduced by 75% for the week following the reaction, then increased by 25% per week to the full dose.14

- **Issues with Self-Injected Disease-Modifying Therapies**

**Adherence** Adherence to injectable medications is a significant problem, with 22% to 59% discontinuation. Realistic therapy expectations, higher educational levels, and higher self-efficacy improve adherence; depression and cognitive problems lower adherence.19

**Patient Education** Refer to Table 30–4 for patient self-injection education.

- **Teriflunomide**

**Pharmacology and Mechanism of Action** Teriflunomide’s mechanism of action may include:
- Cytostatic effect on rapidly dividing B- and T-cells by inhibiting dihydro-orotate dehydrogenase
- Inhibiting T-cell activation, entry to the CNS, and secretion of proinflammatory cytokines

**Pharmacokinetics** Half-life of teriflunomide is 2 weeks; taking 3 months to achieve steady-state concentrations. Metabolized by the liver, it is contraindicated in hepatic failure. Teriflunomide inhibits CYP2C8 and induces CYP1A2 and CYP2C9. It undergoes significant enterohepatic circulation; its half-life is substantially reduced by cholestyramine.

**Efficacy** Teriflunomide reduces relapse rate and progression of disease for relapsing forms of MS.20 It also prevents CIS from converting to clinically definite MS.21

**Adverse Effects** Teriflunomide is generally well tolerated. If patients develop liver injury, teriflunomide must be stopped and accelerated elimination undertaken. Patients should be screened for tuberculosis prior to initiating therapy.20

---

**Patient Encounter, Part 1**

A 23-year-old white woman visits the emergency department today with complaints of loss of visual acuity in her left eye with some eye pain that developed over several hours. She has never experienced symptoms like this previously. She has been generally healthy and is up to date on her vaccinations. She has moved to your area to attend university. Before that, she lived in Maine her entire life.

What information is suggestive of multiple sclerosis (MS)?

What risk factors does she have for MS?

What additional information or testing would assist in making the diagnosis of MS?

What treatment could be provided to the patient for the current acute event?

Dimethyl Fumarate

Pharmacology and Mechanism of Action Dimethyl fumarate is thought to treat MS in the following ways:

- Shift cytokine production from a proinflammatory state to an anti-inflammatory state
- Prevent macrophage entry into the CNS by an unknown mechanism
- Stabilization of transcription factor nuclear (erythroid-derived) related factor which may reduce oxidative stress

Efficacy Dimethyl fumarate reduced relapses approximately 50%. It slowed MS progression in some studies.

Adverse Effects Dimethyl fumarate causes a transient, dose-dependent flushing sometimes with itching. Likely due to histamine release, incidence decreases after the first month and may be improved by slower dose titration, administration with food, and/or H2-blocking antihistamines. Gastrointestinal adverse effects may be lessened with a slow dose increase and administration with food.

Fingolimod

Pharmacology and Mechanism of Action Fingolimod is a sphingosine 1-phosphate receptor modulator. It retains T-cells in lymphoid tissues, depleting peripheral blood and CNS lymphocytes. Fingolimod also binds to sphingosine 1-phosphate receptors in the brain where may reduce inflammatory cytokines.

Pharmacokinetics Fingolimod is highly protein bound with a long half-life of 8 to 9 days (steady-state concentrations achieved in 1-2 months).

Efficacy Treatment reduced the annualized relapse rate to 0.18 compared with 0.40 for placebo. It also slowed MS progression.

Adverse Effects Fingolimod reduces circulating lymphocytes by about 75%; infections and malignancies are concerns. Sphingosine 1-phosphate receptors elsewhere in the body are associated with first-dose bradycardia, macular edema, and reduced forced vital capacity. Fingolimod is contraindicated in patients with myocardial infarctions, unstable angina, stroke, transient ischemic attacks, or some types of congestive heart failure within the past 6 months or in patients with many types of atrioventricular block, prolonged QT interval, or who are taking class Ia or III antiarrhythmic medicines. Extensive monitoring is required at baseline and for the first dose; monitoring must be repeated if therapy is interrupted.

Natalizumab

Pharmacology and Mechanism of Action Natalizumab is a α4-integrin antagonist; its postulated mechanism of action follows:

- Binds to α4β1 and α4β7 integrins, preventing lymphocyte migration into the CNS and inflammation
- Inhibits binding of α4-positive leukocytes to fibronectin and osteopontin, decreasing the activation of leukocytes already within the CNS

Efficacy Treatment with natalizumab reduced relapses by 68% at 1 year and disability by 42% at 2 years versus placebo.

Adverse Effects Hypersensitivity reactions (itching, dizziness, fever, rash, hypotension, dyspnea, chest pain, and anaphylaxis) have been observed, usually within 2 hours of administration. If hypersensitivity occurs, natalizumab is discontinued. A separate infusion reaction (headache, dizziness, fatigue, nausea, sweats, and rigors) may occur within 2 hours of dosing. Histamine...
1 and 2 receptor blockers can be used to prevent these symptoms, and discontinuation is not required. A serious, but rare, adverse effect is progressive multifocal leukoencephalopathy (PML). PML, caused by the JC polyomavirus virus, is rapidly progressive and often results in death or permanent disability. Though most associated with natalizumab, it has been reported in two patients treated with dimethyl fumarate. Specific recommendations are to test for JC virus, avoid natalizumab in immunocompromised patients; carefully assess for immune compromise in patients previously treated with immunosuppression, radiation therapy, or chemotherapy; use only as monotherapy, and carefully monitor patients. Risk of PML increases with increased infusions. Vigilance is paramount because PML can mimic symptoms associated with MS.

Due to this risk, natalizumab is distributed through a restricted program. These concerns lead to the recommendation that natalizumab be reserved for patients with rapidly advancing disease who have failed other therapies. Antinatalizumab antibodies develop in 9% to 12% of patients. If patients have antibodies 6 months after start of therapy, relapse rates and disability increase; antibody development is also associated with hypersensitivity reactions.

**Mitoxantrone**

**Pharmacology and Mechanism of Action** Mitoxantrone is an anthracyclinedione antineoplastic; the mechanisms of action important for MS include:

- Causes apoptosis in T-cells and APCs, preventing initial T-cell activation
- Inhibits DNA and RNA synthesis, decreasing proliferation of T cells, B cells, and macrophages
- Decreases cytokine release, preventing inflammation
- Inhibits macrophages, preventing myelin degradation

**Efficacy** Mitoxantrone is indicated for secondary-progressive MS, progressive-relapsing MS, and for patients with worsening relapsing-remitting MS. It reduces the relapse rate and attack-related MRI outcome measures and MS progression.

Because of its potential for significant toxicities, mitoxantrone is reserved for patients with rapidly advancing disease who have failed other therapies.

**Adverse Effects** Blush discoloration of the sclera and urine lasts 24 hours or more postinfusion. Transient leukopenia and neutropenia are common. Amenorrhea may be permanent.

Cardiotoxicity is a serious adverse effect. Mitoxantrone should not be used in patients with baseline cardiomyopathy, even if asymptomatic. Cyclooxygenase-2 inhibitors potentially worsen cardiac toxicity and should be avoided. Maximum lifetime dose of mitoxantrone is 140 mg/m².

Acute myelogenous leukemia occurred in 0.07% of mitoxantrone-treated patients, appearing within 2 to 4 years of initiating mitoxantrone and responsive to standard therapy.

**Dosing and Administration** Mitoxantrone is infused intravenously over 30 minutes to reduce cardiotoxicity. In standard dosing regimens, mitoxantrone is administered every 3 months. Some centers have used mitoxantrone as induction therapy in patients with very active MS. With this strategy, mitoxantrone either at usual or slightly higher dose is given for a short period of time. This treatment may be followed by β-interferon or glatiramer acetate. These regimens have been effective at reducing relapses and progression in small numbers of patients.

**Other Therapy Considerations**

**Pregnancy** Because MS affects many women of childbearing age, the teratogenic effects of medications is concerning. Women generally experience a decrease in relapses during the second and third trimesters of pregnancy with an increase in the first 3 months postpartum. Although none of the disease modifying therapies is recommended for use during pregnancy, data from pregnancy registries demonstrate no adverse outcomes with interferon β, glatiramer acetate, and natalizumab. Fetal risk is unknown for dimethyl fumarate. Sphingosine 1-phosphate receptors are important in fetal formation, thus fingolimod should be discontinued for at least 2 months before conception to allow for its elimination. Mitoxantrone and teriflunomide are contraindicated during pregnancy and teriflunomide is contraindicated for men who have sexual intercourse with women who may become pregnant. Because of the long half-life of teriflunomide, accelerated elimination is recommended for women who wish to become pregnant.

**Vaccinations** Patients taking teriflunomide, mitoxantrone, or fingolimod should not receive attenuated live virus vaccines. Vaccines may be less effective while on fingolimod, and vaccines should be held for 4 to 6 weeks after a mitoxantrone dose.

**Choosing Therapy** There is no consensus on the best medication for initial therapy. Figure 30–4 suggests a treatment approach.

**Outcome Evaluation**

- Assess symptom changes periodically.
- In β-interferon-treated patients with frequent relapses, test for neutralizing antibodies.
- Monitor medication-specific adverse effects (see Tables 30–1 and 30–3).
- Assess adherence.

**FIGURE 30–4.** Treatment algorithm for CIS and relapsing-remitting MS. A definition of aggressive multiple sclerosis has been proposed as follows: two or more relapses in the preceding year and two or more gadolinium-enhancing lesions on brain MRI scans or a significant T2 lesion burden.
Patient Encounter, Part 2

**PMH:** None

**FH:** No family history of MS. Both parents alive and well. No siblings

**SH:** Graduate student in economics. Single. She does not smoke, drink alcohol, or use illicit drugs

**Allergies:** NKDA

**Meds:** None

**ROS:** (–) N/V/D, HA, SOB, chest pain, cough

**PE:**

**VS:** 126/74, P 70, RR 18, T 38°C (100.4°F)

**Skin:** Warm, dry

**HEENT:** Left pupillary response to light is sluggish, decreased visual acuity left eye

**CV:** RRR, normal S1 and S2, no m/r/g

**Abd:** Soft, NT/ND

**Neuro:** A & O × 3; CN II-XII intact, end point nystagmus on lateral gaze bilaterally

**Motor:** Mild weakness in right arm, poor finger-to-nose left upper extremity

**Labs:** WNL

**Imaging:** T2-weighted MRI shows a gadolinium-enhancing T2-weighted lesion on the left optic nerve and two nonenhancing T2-weighted white matter lesions near the cortex (juxtacortical region)

**Given this additional information, what is your assessment of the patient’s condition?**

**Identify your treatment goals for this patient.**

**What pharmacologic alternatives are available for her?**

**What counseling points will you give the patient for administration of the chosen therapy?**

**Symptomatic Therapies**

Symptoms most unique to MS are fatigue, spasticity, impaired ambulation, and pseudobulbar affect. Treatment of other important symptoms such as urinary incontinence, pain, depression, cognitive impairment, and sexual dysfunction is addressed elsewhere in this text.

**Fatigue** There are nonpharmacologic and pharmacologic strategies for coping with fatigue (Table 30–5). Medicines should be reviewed to identify possible contributors to fatigue. Pharmacologic management of fatigue includes amantadine or stimulants; however, efficacy evidence is limited.

**Spasticity** Spasticity treatment goals are patient specific. For ambulatory patients, reducing spasticity may improve mobility.

For bed-bound patients, treating spasticity may relieve pain and facilitate care. Physical therapy is a nonpharmacologic treatment for spasticity.** KEY CONCEPT **MS patients must be treated with agents specific for upper motor neuron spasticity (Table 30–6). MS spasticity is classified as focal or generalized. If the spasticity involves only one muscle group, it is focal and may benefit from botulinum toxin administration. Systemic medications are used for generalized spasticity. No conclusion can be reached regarding efficacy superiority of one agent.

**Impaired Ambulation** Nonpharmacological treatment includes assistive devices, physical therapy, and/or exercise. Extended-release dalfampridine is indicated for improvement in walking speed.

### Patient Encounter, Part 3

The patient begins therapy with teriflunomide 14 mg orally daily. She does very well with no relapses and minimal adverse effects for 2 years during which time she marries. At her next neurology appointment, she states that she would like to begin a family in the next 6 months. She also reports that she is having episodes of unexpected crying, but she does not endorse symptoms of depression. She is diagnosed with pseudobulbar affect.

**How will you respond to her interest in becoming pregnant?**

**What treatment will you recommend for her MS?**

**What treatment should you consider for pseudobulbar affect?**

### The Patient Care Process

**Patient Assessment:**
- Based on physical exam and review of systems, determine whether patient is experiencing a MS exacerbation currently. Determine presence of any symptoms such as urinary incontinence.
- Review the medical history and MRI findings. Does the patient have CIS? Does patient have aggressive MS (see Figure 30–4)? Is patient pregnant? Does patient want to become pregnant?
- Conduct a medication history (including prescription and nonprescription medications). Has patient been treated with any MS medications or immunosuppressants previously? Is patient experiencing adverse effects?
- Review available laboratory tests, especially leucocytes and liver function tests.

**Therapy Evaluation:**
- If patient is already receiving disease-modifying or symptomatic pharmacotherapy, assess efficacy, safety, and patient adherence. Are there any significant drug interactions?
- Determine if patient has prescription coverage or if recommended agents are included on patient’s insurance formulary. If necessary, obtain prior authorizations.

**Care Plan Development:**
- Treat any relapses with IV or oral corticosteroids.
- Work with patient to select therapy, considering:
  - Route of administration
  - Frequency of administration
  - Adverse-effect profile and other concerns (eg, neutralizing antibodies)
  - Cost, including preauthorization needs for patient’s insurance.
- Obtain required baseline laboratory studies (see Table 30–5).
- Educate patient regarding self-injection, if necessary (see Table 30–4), and adherence.
- Initiate needed symptomatic treatments.
- Address any concerns about MS and its management.

(Continued)
The Patient Care Process (Continued)

- Refer patient to the National MS Society for information, newsletters, and local support groups (www.nationalmssociety.org).
- Instruct patient to contact clinician for any sudden symptom changes suggestive of relapse.

Follow-Up Evaluation:
- Monitor patient for efficacy and adverse effects of disease-modifying and symptomatic therapies every 3 months for the first year and every 6 months thereafter and as required for therapy (see Tables 30–2 and 30–5).
- Obtain MRI annually or more frequently as dictated by symptoms and selected therapy.
- Assess adherence with medications at each visit.

This potassium channel blocker prolongs action potentials, improving conduction in demyelinated neurons. Not all patients respond; response can be assessed at 2 months. Urinary tract infections, insomnia, dizziness, headache, nausea, asthenia, back pain, and balance disorder all occur frequently with dalfampidine. Seizures are an uncommon adverse effect; patients with seizure disorders should not receive dalfampridine.

**Pseudobulbar Affect** Ten percent of patients with MS develop pseudobulbar affect, characterized by inappropriate laughing or crying and causing social isolation. Dextromethorphan prevents the release of excitatory neurotransmitters. Low-dose quinidine blocks first-pass metabolism of dextromethorphan and increases serum concentrations. A 49% decrease in episodes was seen with treatment.

**Outcome Evaluation**
- Assess improvement/recurrence of symptoms.
- Monitor adverse effects of medications.
- Monitor adherence.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the epidemiology and social impact of epilepsy.
2. Define terminology related to epilepsy, including seizure, convulsion, and epilepsy.
3. Describe the basic pathophysiology of seizures and epilepsy.
4. Differentiate and classify seizure types given a description of the clinical presentation of the seizure and electroencephalogram.
5. Identify key therapeutic decision points and therapeutic goals in the treatment of epilepsy.
6. Discuss nonpharmacologic treatments for epilepsy.
7. Recommend an appropriate pharmacotherapeutic regimen with monitoring parameters for the treatment of epilepsy.
8. Devise a plan for switching a patient from one antiepileptic regimen to a different regimen.
9. Manage potential drug interactions with antiepileptic drugs.
10. Determine when and how to discontinue antiepileptic drug therapy.
11. Educate a patient or caregiver on epilepsy and pharmacotherapy for this disorder.

EPIDEMIOLOGY, SOCIAL IMPACT, AND ETIOLOGY

Epidemiology

Epilepsy is a disorder that afflicts approximately 2 million individuals in the United States, with an age-adjusted prevalence of approximately 4 to 7 cases per 1000 persons.1 The incidence of epilepsy in the United States is estimated at 35 to 75 cases per 100,000 persons per year.2,3 In developing countries, the incidence is higher at 100 to 190 cases per 100,000 persons per year. About 8% of the US population will experience a seizure during their lifetime. New-onset seizures occur most frequently in infants younger than 1 year of age and in adults after age 55.4

Social Impact

Epilepsy has a profound impact on a patient’s life. Due to restrictions on driving in all states, individuals who have recently had a seizure face major impediments to engaging in simple activities.5 Fifty percent of patients with epilepsy report cognitive and learning difficulties.6,7 Transportation and educational difficulties combine with persistent seizures to cause unemployment or underemployment, and as a result, problems with paying for health care. Additionally, the social stigma of embarrassment or injury due to seizures in public results in isolation of the patient. Patients with epilepsy often depend on caregivers to assist with medications, transportation, and ensuring the patient’s safety, so they should be informed about treatments and managing seizures.

Etiology

In approximately 80% of patients with epilepsy, the underlying etiology is unknown.8 The most common causes of epilepsy are head trauma and stroke. Developmental and identifiable genetic defects cause about 5% of cases. Genetic causes are presumed in up to 25% of patients, but are often unproven. Brain tumors, central nervous system (CNS) infections, and neurodegenerative diseases are other common causes. Human immunodeficiency virus infection and neurocysticercosis infection are also important causes.

Isolated seizures can be caused by stroke, CNS trauma, CNS infections, metabolic disturbances (eg, hyponatremia, hypoglycemia), and hypoxia. If these causes of seizures are not corrected, they may lead to the development of epilepsy. Drugs commonly associated with causing seizures are tramadol, bupropion, theophylline, some antidepressants, some antipsychotics, amphetamines, cocaine, imipenem, lithium, excessive doses of penicillins or cephalosporins, and sympathomimetics or stimulants.

PATHOPHYSIOLOGY

Seizures

Regardless of the underlying etiology, all seizures involve a sudden electrical disturbance of the cerebral cortex. A population of neurons fires rapidly and repetitively for seconds to minutes. Cortical electrical discharges become excessively rapid, rhythmic, and synchronous. This phenomenon is presumably related...
to an excess of excitatory neurotransmitter action, a failure of inhibitory neurotransmitter action, or a combination of the two. In individual patients, it is usually impossible to identify which neurochemical factors are responsible.

**Neurotransmitters**
The major excitatory neurotransmitter is glutamate. When glutamate is released from a presynaptic neuron, it attaches to receptors on the postsynaptic neuron. The result is opening of membrane channels to allow sodium or calcium to flow into the postsynaptic neuron, depolarizing the neuron and transmitting the excitatory signal. Many antiepileptic drugs (AED) (eg, phenytoin, carbamazepine, lamotrigine) work by interfering with this mechanism, blocking the release of glutamate or by blocking sodium or calcium channels. At usual doses, these drugs typically do not block normal neuronal signaling, only the excessively rapid firing characteristic of seizures, usually not affecting normal brain function.

The major inhibitory neurotransmitter is y-aminobutyric acid (GABA). It attaches to neuronal membranes and opens chloride channels. When chloride flows into the neuron, it becomes hyperpolarized and less excitable. This mechanism is probably critical for suppressing seizure activity. Barbiturates and benzodiazepines primarily act to enhance the action of GABA.

Cortical function is modulated by many other neurotransmitters, but their role in the action of AEDs is poorly understood.

**Neuronal Mechanisms**
- Seizures originate in a group of neurons with abnormal electrical behavior, presumably due to an imbalance of neurotransmitter function. In individual neurons, firing is excessively prolonged and repetitive. Instead of firing a single action potential, these neurons stay depolarized too long, firing many action potentials. This long, abnormal depolarization is called a paroxysmal depolarizing shift (PDS).
- Excessive electrical discharges can spread to adjacent neurons or distant ones connected by fiber tracts. The seizure spreads to other areas of the brain, by recruiting neurons into uncontrolled firing patterns. Recruited neurons may not be abnormal, but are diverted from their normal functioning to participate in the excessive discharges. The area of spread determines the clinical manifestations of the seizure.

Nearly all seizures stop spontaneously, because brain inhibitory mechanisms overcome the abnormal excitation.

**Epilepsy**
Epilepsy is the tendency to have recurrent, unprovoked seizures. A recent statement by the International League Against Epilepsy (ILAE) recommends that this definition include persons with a single seizure, if they have at least a 70% chance of having another seizure. Practically, this defines two populations of patients who should be treated, and implies a permanent change in cortical function, rendering neurons more likely to participate in a seizure discharge. This process is called epileptogenesis, and the exact way in which it occurs is unknown. A process called kindling is considered similar to epileptogenesis in humans, and occurs in animals after prolonged, intermittent electrical brain stimulation.

Epilepsy may develop days, months, or years after a brain insult. It may be that a small group of abnormal neurons causes adjacent or connected normal neurons to gradually become abnormal. When a network of abnormal neurons becomes sufficiently large, it is capable of sustaining an excessive firing pattern for at least several seconds: a seizure. This hyperexcitable network of neurons is the seizure focus.

If the change in cortical electrical characteristics is permanent, why do seizures not occur all the time? This is probably because the occurrence of an individual seizure depends on an interplay of environmental and internal brain factors that intermittently result in loss of the normal mechanisms that control abnormal neuronal firing. Some causes of seizures are sleep loss and fatigue, but it is impossible to determine what triggers a specific seizure.

Epilepsy may remain stable, decrease in severity, or worsen over time. Repeated seizures may cause further damage to the cortex and loss of neurons, especially inhibitory neurons. Reorganization of connections between groups of neurons may strengthen excitatory connections and weaken inhibitory connections.

There are many reasons for controlling seizures completely. Epilepsy is associated with an increased mortality rate, from injuries with seizures or sudden death. Early control of epileptic seizures may reduce the possibility of permanent changes in brain function, although this hypothesis is unproven.

**Genetic Factors**
Patients with seizures may be concerned that their children or other family members will inherit epilepsy. Patients with acquired causes of seizures, such as head trauma or stroke, will not transmit epilepsy. Some patients may have inherited epilepsy. Most of these individuals have primary generalized epilepsy, and develop seizures during childhood. However, the hereditary tendency is weak. Complex inheritance patterns are usually seen, indicating the likely involvement of several abnormal genes or other factors for seizures to occur in offspring. Most patients can be reassured that their children and siblings are unlikely to develop epilepsy.

**SEIZURE CLASSIFICATION AND PRESENTATION**

**General Principles**
Careful diagnosis and identification of seizure types is essential to proper treatment of epilepsy. Numerous schemes and descriptions of seizures exist, but the ILAE has established the currently accepted standard for classifying epileptic seizures (Figure 31–1) and epilepsies or epilepsy syndromes (Table 31–1). Classification of epileptic seizures is based on electroencephalographic (EEG) findings combined with the clinical symptoms or semiotics of the seizure events. Clinical presentation of seizures varies widely depending on the region and amount of brain involved in the seizure.

**Primary Generalized Seizures**
If the entire cerebral cortex is involved in the seizure from the onset, the seizure is classified as primary generalized. This category is now referred to as “genetic generalized seizures,” the apparent cause of most of these syndromes. Types of primary generalized seizures are: Tonic-clonic, Absence, Myoclonic, and Atonic.

**Partial Seizures**
When the seizure begins in a localized area of the brain, it is defined as partial. There are three types of partial seizures in the current classification system (see Figure 31–1): Simple, Complex, and Secondarily generalized.
Epilepsy Syndromes

Classification of epilepsies and epilepsy syndromes is helpful in determining appropriate pharmacotherapy. This classification scheme is based on the type of seizures and the presumed cause: Idiopathic (Genetic) epilepsies, Symptomatic epilepsies, and Cryptogenic (Cause Unknown) epilepsies.

A complete description of a patient’s epilepsy should include the seizure type with the epilepsy or syndrome type (eg, idiopathic, symptomatic, cryptogenic).

Commonly encountered epilepsy syndromes are: Juvenile myoclonic epilepsy (JME), Lennox-Gastaut syndrome (LGS), Mesial temporal lobe epilepsy (MTLE), and Infantile spasms (West’s Syndrome).

Other Classifications

A new ILAE classification system improves the description of the seizure type and epilepsy, and will be finalized soon. The scheme involves five axes:

Axis 1: Description of the seizure event
Axis 2: Epileptic seizure type or types
Axis 3: Any syndrome type
Axis 4: Etiology when known
Axis 5: Degree of impairment by the epilepsy

The new system replaces “partial seizures” with “focal seizures”, “idiopathic epilepsies” with “genetic epilepsies”, and “cryptogenic epilepsies” with “epilepsies of unknown cause.”

DIAGNOSIS

A correct and accurate diagnosis is essential prior to starting pharmacotherapy. A distinction between a single seizure and epilepsy should be made, and other seizure-like disorders (eg, syncope, psychogenic, nonepileptic events, anxiety attacks, cardiac arrhythmias, hypoglycemia, transient ischemic attacks, tics, and complicated migraine headaches) should be ruled out. Seizures are typically brief spells, lasting less than 5 minutes. However, prolonged seizures lasting greater than or equal to 5 minutes or occurring one after another without recovery in between are status epilepticus, which requires immediate medical attention (Chapter 32).

A proper diagnostic workup of a patient presenting with seizures includes the following elements:

- Complete neurologic examination
- EEG
- Laboratory tests (complete blood count [CBC], liver function tests [LFTs], serum chemistry)
- Neuroimaging (preferably magnetic resonance imaging [MRI])
Clinical Presentation and Diagnosis

**Presentation**
- Episodes of sudden and brief loss of consciousness
- Episodes of uncontrolled jerking of groups of muscles
- Sudden unexplained falls
- Sudden and brief episodes of confusion

**Diagnosis**
- Thorough clinical history, including a complete description of the episodes
- Complete neurological physical examination
- Imaging of the brain: preferably a MRI, but a computerized tomogram (CT) of the brain may be used in absence of a MRI
- Laboratory tests: serum electrolytes, complete blood count, renal function, and liver function
- Electroencephalogram (EEG) recording: may be done with special techniques, including hyperventilation and photostimulation. Sleep deprivation may also be used
- Video-electroencephalogram (VEEG)

Many of the tests are done to rule out other causes of seizures (eg, infection, electrolyte imbalance), and in most patients will be normal. Often the EEG appears normal between seizures. Sleep deprivation, photic stimulation, prolonged (greater than 20 minutes) EEG recording, and 24-hour EEG monitoring with video correlation can be done to capture seizure or seizure-like activity on the EEG.

**TREATMENT**

**Desired Outcomes**
- The ultimate outcome goal for any patient with epilepsy is elimination of all seizures without adverse effects of the treatment. An effective treatment plan allows the patient to pursue a normal lifestyle with complete control of seizures. The treatment should enable the patient to drive, perform well in school, hold a reasonable job, and function effectively in the family and community. However, 30% to 50% of patients are not able to fully achieve these outcomes. In these cases, the goal of therapy is to provide a tolerable balance between reduced seizure severity and/or frequency and medication adverse effects, enabling the individual to have a lifestyle as nearly normal as possible.

**General Approach to Treatment**
- Once it is concluded that the patient has seizures, the type of seizure and epilepsy syndrome, if any, must be determined.

  **KEY CONCEPT** Selection of appropriate pharmacotherapy depends on distinguishing, identifying, and understanding different seizure types. Without an accurate classification of the seizure type, it is possible to select a medication that is ineffective or even harmful to the patient.

  **KEY CONCEPT** Prior to starting pharmacologic therapy, it is essential to determine the risk of having a subsequent seizure. If there is an underlying treatable cause, such as hyponatremia or a CNS infection, the risks of another seizure and the development of epilepsy are very small. In these cases, the only necessary pharmacotherapy is to correct the underlying problem and possibly use an AED short-term. Risk factors for repeated seizures in patients without an underlying disorder include:
  - Structural CNS lesion
  - Abnormal EEG
  - Partial seizure type
  - Positive family history
  - Postictal motor paralysis

If no risk factors are present, the risk of another seizure is 10% to 15%. However, if two or more risk factors are present, the risk of another seizure is 100%. If the estimated risk is over 70%, an epilepsy diagnosis is plausible. When sufficient evidence is available to determine the patient has seizures and is at risk for another seizure, pharmacotherapy is usually started (Figure 31–2). The patient should be in agreement with the plan, be willing to take the medication, and be able to monitor seizure frequency and adverse drug effects. **KEY CONCEPT** Mechanisms of action, effectiveness for specific seizure types, common adverse effects, and potential drug interactions are key elements in selecting a medication. Other patient factors such as gender, concomitant drugs, age, economic factors, and lifestyle also need to be considered.

**Nonpharmacologic Therapy**
- Nonpharmacologic treatments for epilepsy are available. For some patients, surgery is the treatment approach with the greatest probability of eliminating seizures. The most common surgical approach for epilepsy is temporal lobectomy. When the seizure focus can be localized and it is in a region of the brain that is not too close to critical areas, such as those responsible for speech or muscle control, surgical removal of the focus can result in 80% to 90% of patients becoming seizure free. According to a National Institutes of Health Consensus Conference, three criteria should be met for patients to be candidates for surgery. Other surgical procedures that are less likely to make a patient seizure free include corpus callosotomy and extratemporal lesion removal.

  Vagal nerve stimulation is another nonpharmacologic approach to treating all types of seizures. An unit that generates an intermittent electrical current is placed under the skin in the chest. A wire is tunneled under the skin to the left vagus nerve in the neck and delivers a small electrical stimulus to the vagus nerve. Additional stimulations can be initiated by swiping a magnet over the device located in the chest. This treatment is essentially equivalent to starting a new medication with regard to efficacy, with fewer than 10% of refractory patients becoming seizure free. Vagal nerve stimulation is usually reserved for patients who do not respond to several drugs and are not surgical candidates. Finally, a deep brain stimulation device has been approved for individuals with seizures refractory to other treatments. Some AED therapy is usually continued in patients with devices.

  Another nonpharmacologic treatment is the ketogenic diet. This diet produces a keto-acidotic state through the elimination of nearly all carbohydrates. The diet consists of dietary fats (eg, butter, heavy cream, fatty meats) and protein with no added sugar. Daily urinalysis for ketones is performed to ensure the patient remains in ketosis. Any inadvertent consumption of sugar results in the diet needing to be reinitiated. Pharmacists must be vigilant in maintaining the diet, by determining the sugar or carbohydrate content of medications the patient is taking.
This diet is typically used only in children with difficult-to-control seizures. In certain patients the diet can be extremely effective, resulting in complete seizure control and reduction of AEDs. However, it is difficult to maintain, and palatability of the diet, growth retardation, and hypercholesterolemia are concerns.

**Pharmacologic Therapy**

**Special Considerations**

- Use of AEDs presents some unique challenges.\(^{26}\)

**Michaelis-Menten Metabolism** Phenytoin metabolism is capacity limited. Michaelis-Menten pharmacokinetics occurs when the maximum capacity of hepatic enzymes to metabolize the drug is reached, and this may occur within the normal dose range. The clinical significance is that small changes in doses result in large changes in serum concentrations. Too large a dose change may result in concentration-related toxicity or breakthrough seizures. Individual differences in metabolism, result in a different relationship between dose and serum concentrations. These differences can be defined only by careful use of serum concentration and dosing data. There are numerous schemes for determining appropriate dosage adjustments of phenytoin, but for routine clinical practice, dosage adjustments for adults with normal protein binding of phenytoin and a steady-state serum concentration can be made using the following plan:
  - For serum concentrations less than 7 mcg/mL (mg/L; 28 μmol/L), the total daily dose is increased by 100 mg.
  - For serum concentrations of 7 to 12 mcg/mL (mg/L; 28–48 μmol/L), the total daily dose is increased by 50 mg.
  - For serum concentrations more than 12 mcg/mL (mg/L; 48 μmol/L), the total daily dose is increased by no more than 30 mg.\(^{27}\)

**Protein Binding** Some AEDs, especially phenytoin and valproate, are highly bound to plasma proteins. When interpreting a reported concentration for these drugs, it is important to remember the value represents the total (ie, bound and unbound) concentration in the blood. Because of differences in the metabolism of these drugs, the clinical effects of altered protein binding are different.

Normally, 88% to 92% of phenytoin is bound to plasma protein, leaving 8% to 12% as unbound. The unbound component produces the clinical effect in the CNS, produces dose-related side effects in the CNS and at other sites, distributes to other peripheral sites, and gets metabolized. Certain patient
groups have decreased protein binding, resulting in an increased unbound percentage of drug. These patient groups include:

- Those with kidney failure
- Those with hypoalbuminemia
- Neonates
- Pregnant women
- Those taking multiple highly protein-bound drugs
- Patients in critical care

Due to the Michaelis-Menten metabolism of phenytoin, alterations in its protein binding result in increased concentration-related adverse effects. In patients with suspected changes in protein binding, it is useful to measure unbound phenytoin concentrations.

When valproate protein binding is altered, the risk for severe dose-related adverse effects is less compared with phenytoin. Michaelis-Menten metabolism is not a factor with valproate, so hepatic enzymes are able to efficiently metabolize the additional unbound portion.

**Autoinduction** Carbamazepine is a potent inducer of hepatic microsomal enzymes. It increases the rate of metabolism for many other drugs, and the rate of its own metabolism. Hepatic enzymes become maximally induced over several weeks, necessitating a small initial dose of carbamazepine that is increased over time to compensate for the enzyme induction (Figure 31–3). Most dosage regimens for carbamazepine call for a starting dose that is 25% to 30% of the typical maintenance dose of 15 mg/kg/day. The dosage is increased weekly until the target maintenance dose is achieved within 3 to 4 weeks. Titration of the carbamazepine dose lessens the risk for severe dose-related adverse effects.

**Drug Selection and Seizure Type**

- The key to selecting effective pharmacotherapy is to base the decision on the seizure type. Several consensus treatment guidelines from the Scottish Intercollegiate Guidelines Network (SIGN), the National Institute for Clinical Excellence in the United Kingdom (NICE), the American Academy of Neurology (AAN), and ILAE all link seizure type to the selection of pharmacotherapy (Table 31–2).

Patient Encounter 1: New-Onset Seizures

A 22-year-old man is seen by his physician 4 days after having a generalized tonic-clonic seizure in his college dorm room. The seizure lasted for 5 minutes, according to his roommate. He was confused for several minutes and went to sleep for a few hours after the seizure.

His physical examination is completely normal, and no focal neurologic deficits were observed. An MRI was ordered and reported as right mesial temporal sclerosis. An EEG shows right fronto-temporal sharp waves.

**What additional information is needed to make a decision about pharmacotherapy?**

**How should this information be used to make choices concerning AED therapy?**

During the visit, he mentions several previous brief episodes of loss of consciousness, and friends tell him his left hand fumbles with his shirt. These started a couple of years ago and now occur 2 to 3 days each week.

**Is pharmacotherapy indicated?**

**If it is indicated, what drug should be used, and how should it be started?**

**What adverse effects are important to monitor?**

Three months later he is doing well. He reports no generalized tonic-clonic seizures, and the brief spells are reduced to about 2 per month.

**What adjustments in pharmacotherapy should be made at this point?**

**Is it possible for him to discontinue AED therapy at some time in the future?**

Outside of the evidence-based guidelines, other pharmacologic treatments are commonly used or avoided. For initial treatment of absence seizures, ethosuximide and valproate are used. In absence and myoclonic seizures, carbamazepine, oxcarbazepine, gabapentin, tiagabine, and pregabalin should be avoided due to association with worsening of these seizure types.

**KEY CONCEPT** Antiepileptic drug therapy should usually be initiated carefully using a titration schedule to minimize adverse events. Moderate target doses are chosen until the patient’s response can be further evaluated in the clinic. If seizures continue, the dose is increased gradually until the patient becomes seizure free or stops having seizures.

**FIGURE 31–3.** Carbamazepine serum concentrations with a titration schedule compared to initiation with no titration. Concentrations are expressed in mcg/mL. Conversion of carbamazepine concentrations to μmol/L requires multiplying by 4.23.
adverse effects appear. For some drugs like lamotrigine, specific titration guidelines are established by the manufacturer.

Treatment of refractory seizures (ie, unresponsive to at least two first-line AEDs) is somewhat different. Combinations of drugs may be useful in patients with difficult to control seizures. All AEDs, except ethosuximide, are effective in combination therapy for partial seizures.

### Complications of Pharmacotherapy
- Adverse effects of AEDs are frequently dose limiting or cause a drug to be discontinued. Two types of adverse effects occur with AEDs: serum concentration-related and idiosyncratic (Table 31–3).

Concentration-related adverse effects happen with increasing frequency and severity as the dose or serum concentration of a drug is increased. Common concentration-related adverse effects include sedation, ataxia, and diplopia. Adverse effects are considered one of the AED selection criteria. For example, if a patient has a job that requires mental alertness, it is best to choose an AED that is less likely to cause sedation (eg, lamotrigine).

- Idiosyncratic adverse effects are not dose or concentration related and almost always result in the AED being discontinued. Rash is the most common of these. Severe skin, hepatic, or hematological reactions occur rarely, but are potentially

<sup>b</sup>Not currently available in the United States.

<sup>c</sup>Possibly effective.

<sup>d</sup>Probably effective.

<sup>e</sup>Proven effective.

life-threatening. The AED should be discontinued immediately when these reactions occur. Carbamazepine, phenytoin, phenobarbital, valproate, lamotrigine, oxcarbazepine, and felbamate are most likely to cause reactions. There is a possibility of cross-reactivity for these adverse effects, especially for carbamazepine, phenytoin, phenobarbital, and oxcarbazepine. It is estimated that 15% to 25% of patients who have an idiosyncratic reaction to one drug will have a similar reaction to the other drugs.

### Chronic Adverse Effects

Because AEDs are administered for long periods of time, adverse effects due to prolonged drug exposure are of concern. Some chronic adverse effects associated with AEDs include peripheral neuropathy and cerebellar atrophy. Other chronic adverse effects are extensions of acute adverse effects, for example, weight gain.

Osteoporosis is a major chronic adverse effect of several drugs. Carbamazepine, phenytoin, phenobarbital, oxcarbazepine, and valproate decrease bone mineral density, after 6 months of treatment. The risk of osteoporosis due to chronic AED use is comparable to the risk with chronic use of glucocorticosteroids. Patients taking carbamazepine, oxcarbazepine, phenytoin, phenobarbital, or valproate more than 6 months should take supplemental calcium and vitamin D. Routine monitoring for osteoporosis should be performed every 2 years, and patients should be instructed on ways to protect themselves from fractures.

GABA, γ-aminobutyric acid.

Practical Issues

Comorbid Disease States

Patients with epilepsy often have comorbid disease states. Care must be taken when treating comorbid conditions, as numerous drugs can interact with AED. These interactions necessitate close monitoring for changes in efficacy or increased toxicity, and dosage changes of other drugs may be necessary when an AED is added or removed. Patients with headaches need special attention in the selection of an AED. Agents known to prevent headache (eg, topiramate) may be preferred, and agents associated with increased headaches (eg, lamotrigine, felbamate) may be secondary or tertiary alternatives.

Depression is common in patients with epilepsy. Approximately 30% have symptoms of major depression at some point. Patients with epilepsy should be routinely assessed for signs of depression, and treatment initiated if necessary. Most AEDs can exacerbate depression, and patients should be warned to watch for mood changes. Some AEDs (eg, lamotrigine, carbamazepine, oxicarbazepine) may be useful in treating depression. If treatment for depression is necessary, an agent that is unlikely to increase seizures and does not interact with AEDs should be chosen. However, treatment with an appropriate antidepressant should not be withheld because of a small risk of increasing seizure frequency.

Switching Drugs

Changing from one AED to another can be a complex process. If the first drug is stopped too abruptly, breakthrough seizures may occur. Changes in AED regimens should be done in a stepwise fashion, keeping in mind drug interactions that may be present and may necessitate dosage changes in concomitant drugs. Typically the new drug is started at a low initial dose and gradually increased over several weeks. Once the new drug is at a minimally effective dose, the drug to be discontinued is gradually tapered while the dose of the new drug continues to be increased to the target dose. During a transition between drugs, patients should be cautioned about the possibility of increased seizures or adverse reactions.

Stopping Therapy

Epilepsy is generally considered to be a lifelong disorder requiring ongoing treatment. However, some patients who are seizure free may desire to discontinue their medications. Patients who become seizure free following surgery may have medications slowly tapered starting 2 years after surgery. Many patients will choose to stay on at least one medication, following successful surgery, to ensure they remain seizure free. Discontinuation of AEDs should be done gradually, only after the patient has been seizure free for 2 to 5 years and with careful consideration of factors predictive of seizure recurrence. They are:

- No seizures for 2 to 5 years
- Normal neurologic examination
- Normal intelligence quotient
- Single type of partial or generalized seizure
- Normal EEG with treatment

Individuals who fulfill all of these criteria have a 61% chance of remaining seizure free after AEDs are discontinued. Additionally, there is a direct relationship between the duration of seizure freedom with medications and the chance of remaining seizure free after medications are withdrawn. Withdrawal of AEDs is done slowly, usually with a tapering dose over at least 1 to 3 months.

Dosing

Dosing of AEDs is determined by general guidelines and response of the patient. Serum concentrations may be helpful in benchmarking a specific response. Therapeutic ranges that are often quoted are broad guidelines for dosing, but should never replace careful evaluation of the patient’s response.

Drug Interactions

AEDs are associated with many different drug interactions. Most interactions occur due to alterations in absorption, metabolism, and protein binding. Tube feedings and antacids are known to reduce the absorption of phenytoin and carbamazepime. Phenobarbital and phenytoin are potent inducers of various CYP450 isoenzymes, increasing the clearance of other drugs metabolized through these pathways (Table 31–4). In contrast, valproate is a CYP450 and UDP-glucuronosyltransferase (UGT) isoenzyme inhibitor and reduces the clearance of some drugs. Phenytoin and valproate are highly protein bound and can be displaced when taken together or with other highly protein-bound drugs. For example, when phenytoin and valproate are taken together, there may be increased dose-related adverse effects within several hours of dosing. This can be avoided by staggering doses or giving smaller doses more frequently during the day. Whenever a change in a medication regimen occurs, drug interactions should be considered and appropriate adjustments in dose of AEDs made.

Special Populations

Children and women with epilepsy have unique problems related to the use of AEDs. In children, developmental changes occur rapidly, and metabolic rates are greater than those seen in adults. When treating a child, it is imperative to control seizures as quickly as possible to avoid interference with development of the brain and cognition. AED doses are increased rapidly, and frequent changes in the regimen are made to maximize seizure control. Due to rapid metabolic rates seen in children, doses of AEDs are typically higher on a milligram per kilogram basis compared with adults, and serum concentrations are used more extensively to help ensure an adequate trial of a drug has been given.

For women, the treatment of epilepsy poses challenges, including teratogenicity, breastfeeding, interactions between AEDs and hormonal contraceptives, and reduced fertility. Recommendations are developed for managing women of childbearing potential and who are pregnant (Table 31–5). Several AEDs

Patient Encounter 2: Managing Chronic Adverse Reactions

A 41-year-old woman with complex partial seizures has been treated with phenytoin 400 mg/day for 20 years. Her seizures are well controlled on this regimen, and she works as a pharmaceutical sales representative. She expresses concern about taking the phenytoin for so long.

What chronic adverse effects are important to monitor in this patient?

How should monitoring for these adverse effects be done?

What measures can be taken to prevent these adverse effects?
Neural tube defects (eg, spina bifida, microcephaly, anencephaly) are associated most commonly with valproate and possibly carbamazepine. Additionally, valproate is associated with impaired cognitive development in children born to women taking valproate during pregnancy. It is best to avoid the use of valproate, if possible, in women of childbearing potential. All women of childbearing potential who take AEDs should take 1 to 4 mg daily of supplemental folic acid to reduce the risk of birth defects. Many AEDs are excreted in breast milk. However, infants were exposed to higher concentrations of AED in utero, so it is unclear if drugs in breast milk are harmful to the child. Decisions about breastfeeding are made on an individual basis.

Many AEDs induce hepatic microsomal enzyme systems and reduce the effectiveness of hormonal contraceptives. Women taking AEDs that may reduce the effectiveness of hormonal contraceptives should also use other forms of birth control. In contrast to these interactions, hormonal contraceptives induce glucuronidation of lamotrigine and valproate, and cause reductions in serum concentrations of these drugs during days of the cycle when hormones are taken; serum concentrations increase during days when hormones are not taken. Serum concentrations

<sup>a</sup>Primary route of metabolism.

Patient Encounter 3: Birth Control

A 21-year-old woman comes to clinic to discuss birth control. She is currently taking oxcarbazepine 1200 mg/day for complex partial seizures. Her seizures are well controlled, except for two seizures in the last year when she missed doses due to not getting refills on time. Otherwise she is in good health.

What advice should be given regarding birth control?

What impact will oxcarbazepine have on hormonal contraceptives?

What AEDs should generally be avoided in women of childbearing potential?

What additional medications or supplements should be considered?

### Table 31–5

**Management of AEDs During Pregnancy**

Give supplemental folic acid 1–4 mg daily to all women of childbearing potential

Use monotherapy whenever possible

Use lowest doses that control seizures

Continue pharmacotherapy that best controls seizures prior to pregnancy

Monitor AED serum concentrations at start of pregnancy and monthly thereafter

Adjust AED doses to maintain baseline serum concentrations

Administer supplemental vitamin K during eighth month of pregnancy to women receiving enzyme-inducing AEDs

Monitor postpartum AED serum concentrations to guide adjustments of drug doses
of many AEDs, drop during pregnancy, and dose increases based on frequent serum concentration monitoring is necessary. Due to induction or inhibition of sex hormone metabolism and changes in binding of hormones to sex hormone binding globulin, some AEDs reduce fertility. Valproate has been associated with a drug-induced polycystic ovarian syndrome. Women who experience difficulties with fertility should seek the advice of health care professionals with expertise in fertility.

**KEY CONCEPT** Older adults have the highest incidence of newly diagnosed epilepsy and face unique challenges in treatment. The highest incidence of seizures and epilepsy is in individuals older than 65 years. Cerebrovascular disease, tumors, trauma, and neurodegenerative diseases are the primary causes of epilepsy in this age group. Diagnosis of epilepsy in older adults is difficult. This is due to the subtle symptoms of seizures, often compromised memory in the elderly, and the fact that many elderly live alone. Carbamazepine, lamotrigine, and gabapentin have been studied in older adults, and all are effective in controlling seizures. Fewer adverse events occur with lamotrigine and gabapentin. Elderly patients are more sensitive to adverse events, so smaller doses tend to be used in this age group.

**OUTCOME EVALUATION**

**KEY CONCEPT** Patients receiving AEDs for seizures should have regular monitoring for seizure frequency, seizure patterns, acute adverse effects, chronic adverse effects, comorbid conditions, and possible drug interactions.

**Efficacy**
- Seizure counts are the standard way to evaluate the efficacy of treatment.
- Encourage patients to keep a seizure calendar that notes the time and day a seizure occurs and the type of seizure. Compare seizure counts on a monthly basis to determine the level of seizure control.

**Toxicity**
- Monitor acute toxicity of AEDs at every clinic visit.
- Question patients about common adverse effects of the AEDs they are receiving. Weigh the impact of acute adverse effects against the extent of seizure control. If it is determined, the adverse effects negatively impact the patient more than the extent of seizure control benefits the patient, adjust the therapeutic regimen. Continuously monitor chronic adverse effects of AEDs.

**Comorbid Conditions**
Routinely evaluate patients for signs and symptoms of depression.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of status epilepticus.
2. Explain the urgency of diagnosis and treatment of status epilepticus.
3. Recognize the signs and symptoms of status epilepticus.
4. Identify the treatment goals for a patient in status epilepticus.
5. Formulate an initial treatment strategy for a patient in generalized convulsive status epilepticus.
6. Compare the pharmacotherapeutic options for refractory status epilepticus.
7. Describe adverse drug events associated with the pharmacotherapy of status epilepticus.
8. Recommend monitoring parameters for a patient in status epilepticus.

INTRODUCTION

Status epilepticus (SE) is a neurologic emergency that can lead to permanent brain damage or death. SE is defined as continuous seizure activity lasting more than 5 minutes or two or more seizures without complete recovery of consciousness. Refractory status epilepticus (RSE) is unresponsive to emergent (first-line) or urgent (second-line) therapy.

SE can present as nonconvulsive status epilepticus (NCSE) or generalized convulsive status epilepticus (GCSE). NCSE is characterized by persistent impaired consciousness without clinical seizure activity and is diagnosed with electroencephalography (EEG). GCSE is characterized by full-body motor seizures and involves the entire brain.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of SE in the United States is 12.5/100,000/year, with an in-hospital mortality rate of 9.2%, and an estimated annual direct cost for inpatient admissions of $4 billion. It occurs most frequently in males, African Americans, children, and the elderly. It is important to evaluate etiologies of SE for timely and optimal seizure control. Causes of SE include metabolic disturbances (eg, hyponatremia, hypernatremia, hyperkalemia, hypocalcemia, hypomagnesemia, hypoglycemia); central nervous system (CNS) disorders, infections, injuries; hypoxia; drug toxicity (eg, theophylline, isoniazid, cyclosporine, cocaine). Chronic causes of SE include preexisting epilepsy, chronic alcoholism (withdrawal seizures), CNS tumors, and strokes. In epileptics, the common causes of SE are anticonvulsant withdrawal or subtherapeutic levels.

PATHOPHYSIOLOGY

Status epilepticus occurs when the brain fails to stop isolated seizures, due to a mismatch of neurotransmitters. Glutamate, the primary excitatory neurotransmitter, stimulates postsynaptic N-methyl-D-aspartate (NMDA) receptors, causing neuronal depolarization. Sustained depolarization causes neuronal injury and death. The primary inhibitory neurotransmitter, γ-aminobutyric acid (GABA), opposes excitation by stimulating GABA_A receptors, producing hyperpolarization and inhibition of the postsynaptic cell membrane. GABA-mediated inhibition diminishes with continuous seizure activity, causing a decreased response to GABA-receptor agonists. Seizures lasting more than 30 minutes cause significant injury and neuronal loss because of excessive electrical activity and cerebral metabolic demand.

Decreased GABA_A receptor response and increasing neuronal injury with prolongation of seizure activity necessitates rapid control of SE.

Systemic changes appear in two phases during SE. Phase I occurs during the first 30 minutes, and phase II occurs after 30 to 60 minutes.

Phase I

During phase I, autonomic activity increases, resulting in hypertension, tachycardia, hyperglycemia, hyperthermia, sweating, and salivation. Cerebral blood flow increases to preserve oxygen supply to the brain. Increases in sympathetic and parasympathetic stimulation with muscle hypoxia can cause ventricular arrhythmias, severe acidosis, and rhabdomyolysis which can lead to hypotension, shock, hyperkalemia, and acute kidney injury.
Patient Encounter 1, Part 1

A 79-year-old woman with a history of hypertension, diabetes, and arthritis was admitted with traumatic subdural hematoma after sustaining a fall down a flight of stairs in her home. She underwent surgery 2 days ago to evacuate the hematoma and is currently recovering in the ICU. She was started on fosphenytoin for seizure prophylaxis upon admission along with her home medications. She has only one peripheral IV line and has very poor vascular access. Her nurse reports that a few minutes ago she was alert and awake, but now she is unarousable and is having jerky, convulsive movements on both sides of her body. The doctor evaluates her and the jerky activity stops, but then starts again about 1 minute later. She never regained consciousness between these episodes. Her diagnosis is status epilepticus. Ht 165 cm (5’5”), Wt 133 kg (293 lbs).

**What initial assessments should be performed?**
**What are some possible etiologies for her seizure?**
**What nonpharmacologic interventions need to be performed at this time?**

---

**Clinical Presentation of Status Epileptics**

**General**
The patient may present with or without clinically noticeable seizure activity.

**Symptoms**
- Impaired consciousness ranging from lethargy to coma
- Disorientation after cessation of GCSE
- Pain from associated injuries (eg, tongue lacerations, dislocated shoulder, head trauma, facial trauma)

**Signs**

**Phase I:**
- Generalized convulsions
- Hypertension, tachycardia
- Fever and sweating
- Muscle contractions, spasms
- Respiratory compromise
- Incontinence

**Phase II (greater than 30 minutes of SE):**
- Respiratory failure with pulmonary edema
- Cardiac failure (arrhythmias, shock)
- Hypotension
- Hyperthermia
- Rhabdomyolysis and multiorgan failure

**Laboratory Tests**
- Hyperglycemia (phase I) and hypoglycemia (phase II) can occur
- Hyponatremia, hypernatremia, hyperkalemia, hypocalcemia, hypomagnesemia, and hypoglycemia can cause SE
- The white blood cell (WBC) count may slightly increase
- Abnormal arterial blood gases (ABGs) due to hypoxia and respiratory or metabolic acidosis
- Elevated serum creatinine will be present in renal failure patients
- Myoglobinuria can occur in patients with continuous seizures

**Diagnostic Tests**
- EEG to confirm seizure activity
- CT or MRI may reveal mass lesions or hemorrhage

**CLINICAL PRESENTATION AND DIAGNOSIS**

**History**

*KEY CONCEPT* When a patient presents with seizures, a thorough history is needed to determine the type and duration of previous seizure activity. This will help guide therapy and clarify necessary laboratory and diagnostic tests. A diagnosis of SE can be made when a patient with a history of repeated seizures and impaired consciousness has a seizure witnessed by a health care professional. However, emergent treatment should not be delayed if seizure activity is suspected based on reports from the patient’s family or emergency response personnel.

**Physical Examination**

Once seizures are controlled, a neurologic exam should evaluate the level of consciousness (coma, lethargy, or somnolence), motor function and reflexes (rigid contractions, rigidity, spasms, or posturing), and pupillary response. A physical exam can identify secondary injuries.

**Clinical Symptoms**

- Patients with SE usually present with generalized, convulsive, tonic-clonic seizures. They may also be hypertensive, tachycardic, febrile, and diaphoretic which resolve after seizure termination. A loss of bowel or bladder function, respiratory compromise, and nystagmus may also be observed. When seizure activity exceeds 30 to 60 minutes, muscle contractions may no longer be visible, necessitating an EEG to diagnosis SE. Twitching of the face, hands, or feet may be seen in these comatose patients with prolonged seizures.

**Laboratory Parameters**

*KEY CONCEPT* It is important to obtain a serum chemistry profile to help identify possible causes of SE, such as hypoglycemia, hypotension, or hypernatremia, hypomagnesemia, and hypocalcemia; patients with renal and liver failure are at high risk as well. In febrile patients with elevated white blood count (WBC) counts, active infections should be considered and treated appropriately. Cultures from the blood, cerebrospinal fluid (CSF), respiratory tract, and urine should be collected once seizures are controlled. Computed tomography (CT) or magnetic resonance imaging (MRI) can rule out CNS abscesses, bleeding, or tumors, all of which may be a source of seizures. Order a blood alcohol level...
and urine toxicology screen to determine if SE is caused by alcohol withdrawal, illicit drug use, or a drug overdose. Serum drug levels should be obtained in an overdose situation to rule out toxicity. **KEY CONCEPT** Knowing the cause of SE will guide initial antiepileptic therapy and increase the probability of seizure termination.

In patients taking antiepileptic drugs (AEDs), a baseline serum concentration is useful to determine if the concentration is below the desired range and whether a loading dose (LD) is needed. Albumin levels, renal and liver function tests should also be utilized to assess therapy.

Hypoxia and respiratory or metabolic acidosis are common in patients with SE. Pulse oximetry and arterial blood gas (ABG) measurements are used to assess pulmonary status and determine if airway protection or supplemental oxygen is needed. Metabolic acidosis may resolve on its own without treatment after termination of clinical seizure activity.

**Diagnostic Tests**

EEG is required to identify SE in a comatose patient. Continuous EEG monitoring should be used in patients who remain unconscious after initial antiepileptic treatment, those receiving long-acting paralytic agents, or those requiring prolonged RSE therapy. Treatment should not be delayed while awaiting EEG results. CT and MRI scans are useful to identify traumatic injury, mass lesions, or evidence of infection as the cause of SE.

**TREATMENT**

**Desired Outcomes**

**KEY CONCEPT** The goal of therapy is to terminate physical and electroencephalographic evidence of seizures, prevent recurrence, and minimize adverse drug events. Poor outcomes are associated with prolonged SE and refractory SE. Complications of SE should also be treated.

**General Approach**

The initial approach to SE involves removing the patient from harmful surroundings and ensuring maintenance of airway, breathing, and circulation. Benzodiazepines are the preferred initial drugs to stop acute seizure activity (emergent therapy), followed by an AED (urgent therapy) for suppression of seizures. Medications are given intravenously (IV) for immediate onset of action, but if IV access is not available, select medications may be given rectally, intramuscularly (IM), buccally, or nasally. After seizures stop, clinicians must identify and treat underlying causes of the seizures, such as toxins, hypoglycemia, or brain injury. Patients with known seizure disorders should be evaluated for abrupt cessation of their medications, noncompliance, or drug interactions. Recent guidelines provide treatment algorithms for SE.

**Nonpharmacologic Treatment**

Oxygen administration or intubation for mechanical ventilation should be performed in cases of hypoxia, and temperature management should be considered for febrile seizures. Specialists in neurology or epileptology should be consulted as appropriate. Admission to an intensive care unit (ICU) allows for aggressive treatment and monitoring.

**Pharmacologic Treatment**

**Initial Treatment**

Hypoglycemia-induced SE is treated with IV dextrose. IV thiamine is given to alcoholics prior to administering any dextrose-containing solutions to prevent encephalopathy.

**Benzodiazepines**

Initial or emergent drug therapy begins with IV administration of a benzodiazepine. This class of agents is highly effective in terminating seizures. Intravenous bolus doses of diazepam, lorazepam, and midazolam have been used in SE because of their rapid effects on GABA receptors. Lorazepam is the preferred agent of most clinicians. When treating patients on chronic benzodiazepine therapy, consider using higher doses to overcome tolerance. Diazepam and lorazepam should be diluted 1:1 with normal saline before parenteral administration via peripheral veins to avoid vascular irritation from the propylene glycol diluent.

Diazepam Being extremely lipophilic, diazepam penetrates the CNS quickly, but rapidly redistributes into body fat and muscle.

**Patient Encounter 1, Part 2**

Physical examination and a review of her chart and recent laboratory studies reveal the following additional information about this patient:

**PE:**

**VS:** BP 178/92 mm Hg, pulse 109 beats/min, RR 26 breaths/min, T 39.0°C (102.2°F)

**CNS:** Unresponsive, unarousable

**CV:** Sinus tachycardia; normal S1, S2; no murmurs, rubs, gallops

**Pulm:** Tachypneic; oxygen saturation 88% (0.88) on room air; no rhonchi, wheezes, rales

**Abd:** Deferred

**Exts:** Rhythmic tonic-clonic movements of all extremities

**GU:** Incontinent of urine and stool

**HEENT:** Persistent upward gaze

**Current Meds:**

- Fosphenytoin 100 mg PE IV every 8 hours; famotidine 20 mg IV every 12 hours; metoprolol 50 mg by mouth every 12 hours; insulin glargine 25 units subcutaneous at bedtime; insulin aspart 5 units subcutaneous with meals; acetaminophen/hydrocodone 325 mg/5 mg tablet by mouth every 4 hours as needed for pain; morphine 2 mg IV every 2 hours as needed for pain

**Labs:**

- Sodium 132 mEq/L (132 mmol/L); potassium 4.1 mEq/L (4.1 mmol/L); phenytoin 2.7 mcg/mL (11 μmol/L); albumin 3.5 g/dL (35 g/L); chloride 105 mEq/L (105 mmol/L); carbon dioxide 12 mEq/L (12 mmol/L); blood urea nitrogen 10 mg/dL (3.6 mmol/L); serum creatinine 0.9 mg/dL (80 μmol/L); glucose 54 mg/dL (3.0 mmol/L); WBC 15 × 10⁹/mm³ (15 × 10⁹/L); hemoglobin 9.6 g/dL (96 g/L or 5.96 mmol/L); hematocrit 28% (0.28 volume fraction); platelets 235 × 10⁹/mm³ (235 × 10⁹/L); prothrombin time 12 seconds; international normalized ratio 1.1; activated partial thromboplastin time 28 seconds

**What is your assessment of the cause of this patient’s condition?**

**What pharmacologic interventions need to be performed at this time?**

**Identify your goals of therapy for this patient.**

**What therapies must be instituted next?**
This results in a rapid decline in CNS levels and early recurrence of seizures. Doses can be given every 5 minutes until seizure activity stops or toxicities are seen (eg, respiratory depression). Diazepam can be administered as a rectal gel enabling non-medical personnel to provide timely therapy at home or in public areas. IM administration of diazepam is not recommended because of erratic absorption.

**Lorazepam** Less lipophilic than diazepam, lorazepam has a longer redistribution half-life, resulting in longer duration of action and decreased need for repeated doses. Both lorazepam and diazepam are effective in stopping seizures, but lorazepam is currently preferred due to a longer duration of action. It can be redosed every 5 to 10 minutes (up to a maximum cumulative dose of 8 mg) until seizure activity stops or side effects such as respiratory depression occur. IM administration is not preferred due to slow and unpredictable absorption.

**Midazolam** Midazolam is water-soluble and can be administered intramuscularly, bucally, and nasally. Compared to diazepam and lorazepam, it has less respiratory and cardiovascular side effects. Its short half-life requires that it be redosed frequently or administered as a continuous IV infusion. Liquid or injectable formulations can be given bucally or intranasally (0.3 mg/kg) in pediatric patients. Rapid breathing and increased secretions can interfere with nasal administration. A recent study in adults and children showed that IM midazolam was as safe and effective as IV lorazepam for prehospital termination of seizures.

**Anticonvulsants**

**KEY CONCEPT** After administering the first dose of benzodiazepine, an AED such as phenytoin, valproate sodium, or phenobarbital should be started to prevent further seizures (urgent therapy). AEDs must not be given as first-line therapy since they are infused relatively slowly to avoid adverse effects, delaying their onset of action. If the underlying cause of the seizures has been corrected (eg, hypoglycemia) and seizure activity has ceased, an AED may be unnecessary. This may be reasonable when patients become alert and oriented or if an EEG confirms absence of seizure activity.

After the AED LD is administered, maintenance doses should be initiated to ensure that therapeutic levels are sustained. Chronic and idiosyncratic side effects and potential drug interactions should be considered if the patient continues AED therapy. Drugs should be adjusted for any hepatic or renal dysfunction.

**Phenytoin** The most widely used AED for urgent treatment of SE is phenytoin, which is available in its original form or as a prodrug, fosphenytoin. LDs must be modified in patients already taking phenytoin with subtherapeutic levels in order to avoid toxic serum concentrations. Doses are infused no faster than 50 mg/minute due to risks of hypotension or arrhythmias. Continuous monitoring of ECG and blood pressure is recommended. Maintenance doses can be started 12 hours after the LD. Phenytoin should not be infused with other medications because of stability concerns (it is soluble in propylene glycol and compatible only in 0.9% sodium chloride solutions). It should not be given IM due to its alkalinity. Extravasation of phenytoin can cause local tissue discoloration, edema, pain, and sometimes necrosis (purple glove syndrome). Oral loading is not recommended in SE due to the limitations of single dose absorption (ie, doses greater than 400 mg are not fully absorbed) and delayed peak concentrations when given orally. Obese patients require larger LDs due to a larger volume of distribution. A dosing weight (DW) can be calculated using total body weight (TBW) and ideal body weight (IBW): DW = IBW + 1.33(TBW-IBW). Vd can be calculated as follows: Vd = 0.7 L/kg x DW (in kg). A LD can then be calculated using Vd and a target concentration: LD = Ctarget x Vd. Fosphenytoin Fosphenytoin is a water-soluble, phosphoester prodrug that is rapidly converted to phenytoin in the body. It is compatible with most IV solutions. It is dosed in phenytoin equivalents (PE), and it can be infused up to 150 mg PE/minute. Although it has fewer cardiovascular side effects than phenytoin, clinicians should continuously monitor blood pressure, ECG, and heart rate. Maintenance doses can be started 12 hours after the LD. Paresthesias, especially around the lips and groin are common, but typically resolve within a few minutes and should not necessitate stopping the infusion. If a postload serum level is desired, it should be obtained 2 hours after an IV load.

**Phenobarbital** If phenytoin or fosphenytoin fails to prevent seizure recurrence, phenobarbital can be considered. However, emerging evidence suggests that phenobarbital may not be effective if SE persists despite benzodiazepines and phenytoin. This may be due to progressive resistance of the GABA_A receptor, where barbiturates also act. Adverse reactions of phenobarbital include sedation, hypotension, and respiratory depression; therefore, patients receiving a rapid IV LD of phenobarbital should have hemodynamic monitoring and be mechanically ventilated if at high risk of respiratory compromise. Its long half-life makes it a popular agent for both acute treatment and chronic maintenance therapy or as adjunct therapy to prevent withdrawal seizures when weaning refractory SE patients off pentobarbital infusions.

**Valproate Sodium** Although valproate sodium is not Food and Drug Administration (FDA)-approved for SE, it has been used IV in various types of SE including generalized tonic-clonic, myoclonic, and NCSE. It is particularly useful in patients with

---

**Patient Encounter 2, Part 1**

A 19-year-old man admitted for two reported episodes of intermittent jerking in his left arm that were witnessed by his mother this morning. He is nonresponsive at the time of admission. He does not take any medications and has no allergies to medications. One week ago, he was seen in the emergency department as he was confused and having difficulties walking after being hit in the head with a soccer ball during a tournament. At that time, a CT scan of his head showed no hemorrhage, and he was diagnosed with having a mild traumatic brain injury. Today while the nurse is taking his vital signs, he becomes confused and then unarousable with jerky movements on the left side of his body. His diagnosis is status epilepticus after this seizure activity does not stop over the next 5 minutes.

VS: BP 111/75 mm Hg, HR 108 beats/min, RR 21 breaths/min, T 37°C (98.6°F), Wt 82 kg (180 lb), Ht 185 cm (6'1")

**What is the most likely cause of this patient’s SE?**

**Treatment of Refractory Status Epilepticus**

Seizure activity unresponsive to emergent and urgent therapy is considered RSE. Refractory SE can occur in up to 30% of patients with SE and has a mortality rate approaching 50%. Patients in RSE are unlikely to regain independent function, even if seizures are controlled. Clinical signs may become subtle and an EEG may be required to detect ongoing seizure activity.

Optimal therapy for RSE is undetermined. Clinicians must aggressively investigate and treat possible causes including infection, tumors, drugs or toxins, metabolic disorders, liver failure, or fever. In general, patients with RSE are managed in an ICU where hemodynamic and respiratory support and frequent monitoring are available. Continuous EEG monitoring is essential and should not be delayed. Any AEDs initiated before treatment for RSE should be continued, and their serum levels optimized to

Even SE patients without clinical signs of seizing are at risk for brain damage or even death.

</table>

rate. Despite this, tachyphylaxis can occur, and patients should be switched to another agent if seizures continue.

► Propofol

LDs of the anesthetic propofol can be given every 3 to 5 minutes until clinical response, after which an infusion can be initiated.

Propofol causes hypotension, especially with LDs; therefore, some clinicians avoid LDs and quickly titrate with a continuous infusion. Long-term, high-dose (greater than 80 mcg/kg/min) propofol infusions are associated with rhabdomyolysis, acidosis, and cardiac arrhythmias (propofol-related infusion syndrome), especially in children. It has a very short serum half-life and should be tapered off slowly to avoid withdrawal seizures. Propofol infusions are a source of calories (1 kcal/mL [4.2 kJ/mL]), so nutrition requirements have to be adjusted accordingly.

► Pentobarbital

Barbiturate infusions are reported to be highly effective in treating RSE, but they cause significant hypotension, myocardial and respiratory depression, ileus, and infections. Therefore, patients require mechanical ventilation and invasive hemodynamic monitoring. Patients often require IV vasopressor therapy and total parenteral nutrition. Barbiturates are beneficial in decreasing elevated intracranial pressure (ICP).

A meta-analysis reported a lower incidence of treatment failure with pentobarbital (3%) compared to midazolam (21%) or propofol (20%), although the risk of hypotension requiring vasopressor therapy was higher with pentobarbital. This relative efficacy for pentobarbital must be considered together with its complications when determining which agent to use. Patients who fail midazolam and/or propofol should be switched to pentobarbital.

► Levetiracetam

Although not FDA-approved for SE, levetiracetam does not have the cardiopulmonary, hepatic, and sedative side effects seen with the other agents; nor does it have potentially harmful drug interactions. Both IV and oral formulations have been used in RSE patients as add-on therapy with some success, although it is unclear if levetiracetam would be effective as monotherapy. LDs up to 2000 mg over 15 to 30 minutes in the critically ill have been given with very little toxicity.

► Other Agents

Ketamine, topiramate, and inhaled anesthetics have also been used for RSE. Ketamine is an NMDA receptor antagonist that has been given orally and intravenously for RSE in children. Topiramate is an oral AED with multiple mechanisms of action in RSE. The oral dose in adults ranges from 300 to 1600 mg/day. Children have also been administered topiramate at a starting dose of 2 to 3 mg/kg/day and titrated to a maintenance dose of 5 to 6 mg/kg/day. Topiramate can induce metabolic acidosis, requiring careful monitoring. The inhaled anesthetics, desflurane and isoflurane, require special equipment for administration in an ICU. Lacosamide, an enhancer of slow inhibition of sodium channels, has limited drug interactions. It has been used orally and intravenously in the setting of refractory partial SE.

Special Populations

Certain patients require special considerations due to their altered metabolism, unique volume of distribution, or increased risk for side effects. Although many of these patients are excluded from clinical trials in SE, the standard algorithm for SE still applies in terms of immediate care, assessment, and drugs (see Table 32–2).

► Pediatrics

The treatment approach for SE in children is similar to that in adults with a few exceptions (see Table 32–3). The doses are also weight-based but are typically higher than those used in adults due to faster hepatic clearance. Timely IV access in children may be difficult, so alternate routes of administration have been used,
including intranasal, buccal, rectal, and IM. Early administration of benzodiazepines and reduced time to hospital admission are important in decreasing prolonged seizures.\textsuperscript{42}

\textbf{Geriatrics}

Older adults are often vulnerable because of multiple disease states and polypharmacy. Seizures in older adults often arise from metabolic disorders, drug interactions, or incorrect dosing of medications in patients with impaired renal and hepatic function and decreased protein binding. Clinicians treating older adult patients with SE should investigate drug- and disease state–induced causes, since treating these etiologies alone may terminate seizures. Acute treatment with benzodiazepines and AEDs is no different in older adults, but they may experience more profound sedative and cardiorespiratory side effects. Phenytoin and fosphenytoin LDs should be carefully calculated in older adult whose weights may be overestimated, and who may not tolerate high doses. They should also be infused more slowly to minimize hypotension and arrhythmias. Phenobarbital may cause respiratory depression earlier in older adults, especially after benzodiazepines. Clinicians should consider using smaller doses and evaluate for renal and hepatic insufficiency if repeated doses are to be given.

\textbf{Pregnancy}

The main concern in the treatment of pregnant females in SE is the safety of the fetus which is at risk of hypoxia during periods of prolonged seizures. Although many drugs used in SE are teratogenic, clinicians should still use them acutely to stop seizures, but consider alternative agents for maintenance therapy.\textsuperscript{43} The volume of distribution and clearance of many drugs are increased during pregnancy, and this must be considered when calculating doses.

\textbf{OUTCOME EVALUATION}

Start pharmacologic treatment as soon as possible.

- First-line (emergent) treatment for SE should halt seizure activity within minutes of administration.

- In patients who are unarousable following treatment, confirm termination of seizures with an EEG.

- Perform a physical exam and evaluation of the patient’s laboratory results to help determine if the cause or complications of seizure activity are being appropriately treated.

Once seizure activity has ceased and the patient has stabilized, review the patient’s therapeutic regimen.

- Evaluate and monitor serum trough concentrations of AEDs with defined target ranges to determine patient-specific therapeutic goals.

- In patients with RSE on multiple AEDs, slowly decrease the dose of one drug at a time while continuing to evaluate the patient for seizure activity.

- Continue to monitor AED serum trough concentrations approximately every 3 to 5 days until the AEDs have reached steady-state concentrations.

- Monitor for signs of drug toxicity and seizures until drug concentrations have stabilized.

- Closely evaluate medication profiles, and change drugs or doses to minimize any drug interactions, if possible.

REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of Parkinson disease (PD) related to neurotransmitter involvement and targets for drug therapy in the brain.
2. Recognize the cardinal motor symptoms of PD and determine a patient’s clinical status and disease progression based on the Movement Disorder Society Unified Parkinson Disease Rating Scale (MDS UPDRS).
3. For a patient initiating therapy for PD, recommend appropriate drug therapy and construct patient-specific treatment goals.
4. Recognize and recommend appropriate treatment for nonmotor symptoms.
5. Formulate a plan to minimize patient “off-time” and maximize “on-time” including timing, dosage, and frequency of medications.
6. Recognize and treat various motor complications that develop as PD progresses.
7. Construct appropriate patient counseling regarding medications and lifestyle modifications for a patient with PD.

INTRODUCTION

Parkinson disease (PD) is a slow, progressive neurodegenerative disease of the extrapyramidal motor system. Dopamine neurons in the substantia nigra are primarily affected, and degeneration of these neurons causes a disruption in the ability to generate body movements. Cardinal features of PD include tremor at rest, rigidity, akinesia/bradykinesia, and postural instability. There is no cure, and treatment is aimed at controlling symptoms and slowing disease progression.

EPIDEMIOLOGY AND ETIOLOGY

PD affects approximately 1 million Americans, and a lifetime risk of developing the disease is 1.5%. Median age of onset is 60 years, but about 10% of people with PD are younger than 45 years. The average duration of time from diagnosis to death is about 15 years. Approximately 15% of patients with PD have a first-degree relative with the disease.\(^1\)\(^2\)

The etiology of neuron degeneration in PD remains unknown, but aging has been implicated as a primary risk factor. Other explanations for the cell death may include oxidative stress, mitochondrial dysfunction, increased concentrations of excitotoxic amino acids and inflammatory cytokines, immune system disorders, trophic factor deficiency, signal-mediated apoptosis, and environmental toxins. Conditions that may promote oxidative stress include increased monoamine oxidase-B (MAO-B) metabolism or decreased glutathione clearance of free radicals.\(^2\)\(^3\)\(^4\)\(^5\)

Genetic mutations such as those in LRRK2 have been linked to PD, and particular mutations may predict early versus late onset of the disease.\(^2\)\(^3\) A combination of inducers of cell death and genetic mutations may be at play in the development of PD.\(^2\)

In PD pigmented cells in the substantia nigra that make and store dopamine are lost. When patients are diagnosed, they have lost 50% to 60% of their dopamine neurons located here, and the remaining neurons elsewhere in the central nervous system (CNS) may be dysfunctional. Neurons have lost about 80% of their activity in the striatum at the onset of PD. Cortical Lewy bodies along with Lewy neurites in various CNS locations as well as the GI system may explain some of the nonmotor symptoms of PD.\(^2\)\(^4\)\(^5\)

PATHOPHYSIOLOGY

The extrapyramidal motor system controls muscle movement through pathways and nerve tracts that connect the cerebral cortex, basal ganglia, thalamus, cerebellum, reticular formation, and spinal neurons. Patients with PD lose dopamine neurons in the substantia nigra, located in the midbrain within the brainstem. The substantia nigra sends nerve fibers to the corpus striatum, which is part of the basal gangia in the cerebrum. The corpus striatum is made up of the caudate nucleus and the lentiform nuclei that consist of the pallidum (globus pallidus) and putamen (Figure 33–1). As dopamine neurons die, dopamine-relayed messages cannot communicate to other motor centers of the brain, and patients develop motor symptoms. A variety
of neurotransmitters are active in the basal ganglia, and their concentrations decrease with degeneration. These changes may explain some of the nonmotor symptoms seen in PD. For example, loss of dopamine and norepinephrine neurons in the limbic system is associated with depression and anxiety, while loss of these neurotransmitters along with acetylcholine and serotonin in the limbic system and other regions is associated with cognitive impairment. The disease may begin in the autonomic system, olfactory system, or vagus nerve in the lower brainstem and then spread to the upper brainstem and cerebral hemisphere affecting dopamine pathways later in the course of disease progression. It is essential to rule out drug-induced pseudoparkinsonism. Offending agents include drugs that deplete dopamine such as antipsychotics, metoclopramide, and certain antiemetics such as prochlorperazine. Removing the offending agent generally resolves symptoms.

**Clinical Presentation of PD**

Patients with PD display both motor and nonmotor symptoms. The nonmotor symptoms may precede the motor symptoms.

**Motor Symptoms (Mnemonic TRAP)**
- T = Tremor at rest (“pill rolling”)
- R = Rigidity (stiffness and cogwheel rigidity)
- A = Akinesia or bradykinesia
- P = Postural instability and gait abnormalities

**Nonmotor Symptoms (Mnemonic SOAP)**
- S = Sleep disturbances (insomnia, REM sleep behavioral disorder, restless legs syndrome [RLS])
- O = Other miscellaneous symptoms (problems with nausea, fatigue, speech, pain, dysesthesias, vision, seborrhea)
- A = Autonomic symptoms (drooling, constipation, sexual dysfunction, urinary problems, sweating, orthostatic hypotension, dysphagia)
- P = Psychological symptoms (anxiety, psychosis, cognitive impairment, depression)

**Response Fluctuations (Mnemonic MAD)**
- M = Motor fluctuations (delayed peak, wearing off, random off, freezing)
- A = Akathisia
- D = Dyskinesias (eg, chorea, dystonia, diphasic dyskinesia)

**CLINICAL PRESENTATION AND DIAGNOSIS**

The diagnosis of PD is based substantially on signs and symptoms rather than diagnostic tests or imaging. A single-photon emission computed tomography scan in conjunction with DaTscan,
a radiopharmaceutical contrast agent, may help differentiate PD from other disorders such as essential tremor, but not from similar Parkinson-plus syndromes such as multiple system atrophy or progressive nuclear palsy. Therefore, a thorough patient history and detailed description of symptom onset is essential in making an accurate diagnosis.

**Motor Symptoms**

*PD is a slow, progressive neurodegenerative disease of the extrapyramidal motor system with classic motor symptoms of tremor, rigidity, akinesia/bradykinesia, and postural/gait instability (TRAP).*

The onset of PD is gradual, and impairment of movement may go unnoticed initially. Tremor occurs during rest and disappears with purposeful movement. The hand tremor can appear as if the patient is rolling a pill between his or her fingers. Patients usually describe rigidity as stiffness, and muscles often display uniform resistance on examination. Cogwheel rigidity is found when the examiner extends or flexes the patient’s extremities and feels rhythmical jerking as if hitting a series of teeth on the rim of a wheel. Bradykinesia is defined as hesitancy in movement initiation, slowness in movement performance, or rapid fatiguing during movement. Patients may have a decrease in automatic movements, such as eye blinking, hypomimia, or a decrease in arm swing while walking. Postural instability results from the loss of reflexes necessary to maintain balance when ambulating. Stooped posture resulting in unsteadiness is common. Gait abnormalities may include slow shuffling, leg dragging, festination, propulsion, retropulsion, or freezing. Rigidity and bradykinesia may make handwriting difficult as evidenced by micrographia.

**Nonmotor Symptoms**

Nonmotor symptoms associated with PD may precede the onset of motor symptoms by many years. These commonly include sleep disturbances, autonomic impairment, psychological disturbances, and others such as anosmia or sensory disturbances. Nonmotor symptoms may be a result of PD itself or medications.

Speech problems may manifest as hypophonia, slurring, monotone speech, rapid speech, or stammering. Visual problems such as difficulty reading, double vision, decreased blinking, and burning or itchy eyes are the result of impairment of the ocular muscles.

Because the autonomic nervous system is disturbed in PD, orthostatic hypotension, gastrointestinal (GI), urinary, sexual, and dermatologic symptoms are common. Orthostatic hypotension may cause dizziness, lightheadedness, fainting upon standing, or fall-related injuries. GI symptoms include constipation and dysphagia. Swallowing difficulties may lead to weight loss, diarrhea, and aspiration.

Genitourinary symptoms include incontinence, urgency, and frequency. Symptoms may worsen at night, causing nocturia. Sexual dysfunction manifests as decreased libido or inability to achieve orgasm in both sexes and erectile or ejaculatory dysfunction in men. Dermatologic symptoms include sweating and intolerance to temperature changes.

Psychological symptoms—psychosis, dementia, impaired cognitive function, depression, and anxiety—may occur during the natural course of PD, during symptom exacerbation, or as adverse effects from medications. Psychosis occurs in nearly 30% of PD patients and may include vivid dreams, hallucinations, paranoia, and delusions. Psychosis is rarely seen in untreated patients. Dementia and depression occur frequently with the latter likely due to abnormalities in dopamine and serotonin activity. Some features of PD, such as decreased facial expression and bradykinesia, may make the diagnosis of depression more difficult. Often comorbid with depression, anxiety has been noted in up to 66% of patients with motor fluctuations.

Sleep disorders occur commonly and may be due to loss of neuronal functioning or medication adverse effects. Excessive daytime sleepiness, insomnia, and abnormal sleep events, such as rapid eye movement (REM) sleep behavior disorder (RBD) may occur.

**Motor Complications**

Motor complications occur with disease progression as dopamine reserves are depleted and as a complication of treatment, particularly with levodopa. Motor complications include delayed peak response, early and unpredictable “wearing off,” freezing, and dyskinesias. Dyskinesias include chorea and dystonia. Risk factors for developing motor complications include younger age at diagnosis, high dosage of levodopa, and longer duration and severity of disease. Wearing off can be conceptualized as the therapeutic window of levodopa narrowing over time. The therapeutic window is defined as the minimum effective concentration of levodopa required to control PD symptoms (“on” without dyskinesia) and the maximum concentration before experiencing side effects from too much levodopa (“on” with dyskinesia).

Although the plasma half-life of levodopa is 1.5 to 2 hours, the therapeutic effect in early PD lasts about 5 hours, and the patient experiences no dyskinesias. This is due to supplemental dopamine production in the CNS. As PD progresses, this endogenous supply is decreased, the therapeutic window narrows, and each dose of levodopa acts unpredictably, with the therapeutic effect lasting only 2 to 3 hours. Dyskinesias become more likely to occur during the on state.

The goals of treatment include:

- maintaining patient independence, ADL, and quality of life (QOL)
- minimizing the development of response fluctuations
- limiting medication-related adverse effects

**General Approach to Treatment**

Treatment of PD is categorized into three types: (1) lifestyle changes, nutrition, and exercise; (2) pharmacologic intervention, primarily with drugs that enhance dopamine concentrations; and (3) surgical treatments for those who fail pharmacologic interventions.
Initial treatment depends on the patient’s age, risk of adverse effects, degree of physical impairment, and readiness to initiate therapy. Initiating therapy with levodopa may be more beneficial for mobility than starting with a MAO-B inhibitor or dopamine agonists.24

The 2002 American Academy of Neurology guidelines and 2006 European National Institute for Health and Clinical Excellence guidelines suggest that symptomatic treatment should be delayed until the patient experiences functional disability.25,26 Some data, however, suggest that earlier treatment may delay the progression of disease. In support of this, some clinicians note that progression of symptoms occurs most rapidly around the time of diagnosis and in early PD, and slows later in the disease.27,28 However, studies examining this have design flaws and inconsistent results.12,27 Until current clinical practice guidelines are revised, one must weigh the pros and cons of delaying pharmacotherapy or starting medications early on an individual patient basis.25

Nonpharmacologic Therapy

- **Lifestyle Modifications**

Nonpharmacologic therapy, including education and lifestyle modifications such as exercise, should be started early and continued throughout treatment for PD. These treatments may improve ADLs, gait, balance, and mental health. The most common interventions include maintaining good nutrition, physical condition, and social interactions.130. Coordinated care with an optometrist/ophthalmologist, dentist, dietician, physical therapists, speech therapist, and social worker is needed to maximize patient outcomes. Each of these specialists plays a specific role in the treatment team (Table 33–1).30

## Surgery

As patients develop inadequate control of motor symptoms despite medical treatment, surgery with deep brain stimulation (DBS) may be considered. This procedure electrically stimulates the subthalamic nucleus or globus pallidus interna. DBS may significantly reduce motor symptoms and complications and improve QOL compared to medication management. Trials indicate that targeting the subthalamic nucleus is preferred when a decrease in PD medication use is desired while targeting the globus pallidus may be better suited when dyskinesias are present.31,32 These surgeries are not without risk and are generally

**Patient Encounter, Part 2: Initial Visit—Physical Examination and Diagnostic Tests**

**Chief Complaint:** Increased tremor, rigidity, and slowness, postural instability

**PMH:** Constipation for greater than 10 years

**SH:** Retired. Lives with husband and has two children. Denies alcohol use. Denies smoking

**Meds:** Carbidopa/levodopa 10 mg/100 mg orally—two tablets at 7 AM, one tablet at noon, and one tablet at 7 PM; prochlorperazine 10 mg orally three times a day

**ROS:** (–) Agitation, depression, or psychosis; reports nausea, denies vomiting, diarrhea, HA, dizziness, or pain

**PE:**

- **Gen:** Flat affect, looks older than stated age, speaks softly and often difficult to hear, slow, shuffling gait
- **VS:** BP: sitting 125/80 mm Hg, standing 105/70 mm Hg; P 65 beats/min, RR 18/min, Wt 59 kg (130 lb), Ht 165 cm (65 in)
- **HEENT:** Decreased eye blinking and facial expression, CN II-XII intact, PERRLA, TMs intact
- **CV:** RRR, normal S1, S2; no murmurs, rubs, gallop
- **Abd:** Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly
- **Skin:** Normal
- **Exts:** Mild tremor in both hands and feet. Cogwheel rigidity bilateral elbows, no edema
- **Neuro:** Slow, shuffling gait, sensory function intact, normal muscle strength, normal reflexes, alert, mental status examination normal

**Rating Scales:** Mini Mental Status Exam (MMSE) = Normal 29/30; UPDRS = 50 while “on”

**Labs:** Normal metabolic profile and CBC

utilized after complications with or poor response to medication management.

Pharmacologic Therapy

Drug therapy is aimed at enhancing dopaminergic activity in the substantia nigra. The best time to initiate dopaminergic therapy is controversial and patient specific. Medications help minimize motor symptoms, and improve QOL and ADLs, but they are not curative (Table 33–2).1,2,3,33 PD patients with optimal treatment have greater mortality and morbidity than the general population.1

Choice of pharmacologic agent should be individualized based on patient-specific parameters, and dose frequency should be scheduled based on individual response to maximize "on time" and minimize "off time". Pharmacologic options for PD include anticholinergics (Ach), amantadine, MAO-B inhibitors, dopamine agonists, levodopa/carbidopa, and catechol-O-methyltransferase (COMT) inhibitors. Because most pharmacologic treatments in PD aim to avoid degeneration of the dopaminergic nigrostriatal pathway, it is essential to understand how all drugs may affect dopamine concentrations (Figure 33–2). The American Academy of Neurology and the Movement Disorder Society determined that it is reasonable to start treatment with either levodopa or a dopamine agonist.11–15

Choice of agent varies based on clinical experience and patient preference. Starting with a dopamine agonist may help to delay the onset of dyskinesias and the on and off fluctuations seen with long-term levodopa use. However, this approach may result in less motor benefit and greater risk of hallucinations or somnolence. Levodopa results in greater motor improvement and should be used as initial therapy in the elderly (greater than 75 years) and in those with cognitive impairment.28 Data are insufficient to recommend initiating treatment with combined levodopa and a dopamine agonist. Initiating treatment with anticholinergic medications, amantadine, or MAO-B inhibitors is recommended only for patients who have mild symptoms because they are not as effective as dopamine agonists or levodopa.1,2,11–15,33,34

Medications should be started at the lowest dose and increased gradually based on symptoms (see Table 33–2). Adjust dose timing, frequency, or both based on the patient’s report of "on

FIGURE 33–2. Levodopa absorption and metabolism. Levodopa is absorbed in the small intestine and distributed into the plasma and brain compartments by an active transport mechanism. Levodopa is metabolized by dopa decarboxylase, monoamine oxidase, and catechol-O-methyltransferase. Carbidopa does not cross the blood–brain barrier. Large neutral amino acids in food compete with levodopa for intestinal absorption (transport across gut endothelium to plasma). They also compete for transport into the brain (plasma compartment to brain compartment). Food and Ach delay gastric emptying resulting in levodopa degradation in the stomach and a decreased amount of levodopa absorbed. If the interaction becomes a problem, administer levodopa 30 minutes before or 60 minutes after meals.

time” duration and wearing off symptoms. Dyskinesias related to dopamine concentrations can be managed by decreasing the dose, frequency, or use of medications that may enhance dopamine concentrations. If a dopaminergic medication is to be discontinued, it should be decreased gradually and the patient monitored for worsening of symptoms.

► Anticholinergics

Anticholinergics (Ach) block acetylcholine, decreasing the acetylcholine to dopamine concentration ratio. They minimize rest- ing tremor and drooling, but are not as effective as other agents for rigidity, bradykinesia, and gait problems. Side effects include dry mouth, blurred vision, constipation, cognitive impairment, hallucinations, urinary retention, orthostatic hypotension, temperature sensitivity, and sedation. They are usually avoided or used with caution in patients older than 70 years because of an increased risk of cognitive impairment.\(^1,2,10,29,33\) Ach should be discontinued gradually to avoid withdrawal effects or worsening of symptoms. Additionally, Achs may be associated with an increased incidence of amyloid plaques and neurofibrillary tangles in patients with PD. There is concern that this may translate to an increased risk of Alzheimer disease.\(^19\) Ach decrease gastric motility, which may delay gastric emptying and lead to erratic and decreased levodopa absorption.\(^37\)

► Amantadine

Amantadine is an N-methyl-D-aspartate (NMDA)-receptor antagonist that blocks glutamate transmission, promotes dopamine release, and blocks acetylcholine. It improves PD symptoms in mildly affected patients and may reduce dyskinesia severity and duration.\(^22,38,39\) Patients who develop tolerance to amantadine’s effects may benefit from a drug holiday through a gradual taper to discontinuation to minimize withdrawal effects. Side effects include nausea, dizziness, livedo reticularis, peripheral edema, orthostatic hypotension, hallucinations, restlessness, anticholinergic effects, and insomnia. It should be avoided in the elderly who cannot tolerate its anticholinergic effects.\(^29,33,39\)

► MAO-B Inhibitors

Selegiline and rasagiline selectively and irreversibly block MAO-B metabolism of dopamine in the brain. They may provide a mild symptomatic benefit for patients who choose to delay dopaminergic medications, and they reduce off time when added to levodopa therapy.\(^10–13,39\) Combining selegiline or rasagiline with levodopa in early treatment may delay motor complications.\(^22,27,40\)

Both rasagiline and selegiline are thought to be neuroprotective, but there is no evidence to validate this.\(^41\)

Selegiline is available in an orally disintegrating tablet designed to avoid first-pass metabolism. This improves bioavailability and
decreases serum concentrations of its amphetamine-like metabolite. This metabolite may improve fatigue but conversely may cause insomnia. Thus selegiline should not be dosed in the late afternoon or evening. Side effects of selegiline are minimal but include nausea, confusion, hallucinations, headache, jitteriness, and orthostatic hypotension. Daily doses are limited to 10 mg because MAO-B selectivity may be lost at higher doses increasing the risk of adverse effects and drug interactions.27,28

Rasagiline is less likely to cause insomnia because it is not metabolized to amphetamines. Side effects are primarily GI related. The labeling of rasagiline states that restriction of tyramine-containing foods is not ordinarily required at recommended dosages, but certain foods with extremely high levels of tyramine and exceeding recommend dosing of rasagiline may increase the risk of hypertensive crisis.40

Dyskinesias can be minimized by decreasing the levodopa dose when adding either of these agents. Because of risks of serotonin syndrome and hypertensive crisis, patients should avoid or use these medications cautiously with narcotic analgesics, antidepressants, and other serotonergic agents, or sympathomimetic amines (cold and weight loss products).27,28

▶ Dopamine Agonists

Dopamine agonists bind to postsynaptic dopamine receptors. They are useful as initial therapy, as suggested by the 2010 Scottish Intercollegiate Guidelines. Their advantages include delay of levodopa therapy and smaller risk of developing motor fluctuations during the first 4 to 5 years of treatment. Eventually, they inadequately control the patient’s symptoms, and levodopa will need to be started. In advanced disease, they can be added to levodopa to minimize response fluctuations, decrease off time, improve wearing-off symptoms, allow a reduction in levodopa dose, and improve ADLs.1,2,11,13,34,42

Dopamine agonists include the ergot derivatives (bromocriptine) and the nonergot derivatives (rotigotine, pramipexole, ropinirole, and apomorphine). Generally, the nonergot agents are chosen first over bromocriptine due to a more favorable adverse effect profile and stronger evidence of efficacy.41 If patients fail one dopamine agonist, another can be tried. Although not well established, it appears that bromocriptine 30 mg, ropinirole 15 mg, and pramipexole 4.5 mg are equivalent, and this relationship can be a guide when switching agents. Rotigotine is available as a once-daily skin patch which minimizes pulsatile dopaminergic stimulation.1,28,29,33,38

Common side effects include nausea, vomiting, sedation (highest with apomorphine), pedal edema, orthostatic hypotension (highest with pramipexole) and psychiatric effects that are greater than with levodopa (nightmares, confusion, and hallucinations). Uncommon ergot side effects include painful reddish discoloration of the skin over the shins and pleuropulmonary, retroperitoneal, and cardiac fibrosis.1,10,33,38 Patients’ therapy may be complicated by the dopamine dysregulation syndrome (DDS). This includes an addictive pattern of dopamine agonist use, complex stereotyped behavior known as punding, and impulse control disorders (ICDs) such as gambling or compulsive shopping. Reducing or eliminating the agonist usually resolves these problems.44

Dopamine agonists may cause excessive daytime sleepiness in 50% of PD patients. Sudden sleep attacks may occur and are potentially dangerous if occurring during certain activities such as driving. Modafinil and other agents to promote wakefulness may be used for daytime sleepiness, but use for sleep attacks remains controversial.12,45

All dopamine agonists are metabolized by the liver except pramipexole, which is eliminated unchanged in the urine. Ropinirole is metabolized by cytochrome P450 and subject to drug–drug interactions with drugs that induce (eg, smoking) or inhibit (eg, ciprofloxacin, fluvoxamine, and mexiletine) CYP1A2.29,33

Apomorphine is used subcutaneously for acute off episodes in advanced PD when rapid rescue therapy is needed. It requires premedication with an antiemetic because it causes nausea and vomiting.29,33

▶ Levodopa/Carbidopa

Although levodopa, a dopamine precursor, is the most effective agent for PD, when to initiate therapy remains controversial. Patients experience a 40% to 50% improvement in motor function with levodopa versus 30% with dopamine agonists.1,2,28 However, some argue for delaying treatment with levodopa because approximately 70% of patients experience motor complications within 6 years. Others advocate starting therapy sooner because, historically, patients from the pre-levodopa era who delayed starting levodopa until it became available developed dyskinesias earlier than modern era patients. Delaying levodopa therapy in early disease in favor of other agents may not offer short or long-term benefits.1,2,12,20,29,33

Levodopa is absorbed in the small intestine and peaks in the plasma in 30 to 120 minutes. Excess stomach acid, food, or anticholinergic medications delay gastric emptying and decrease the amount of levodopa absorbed. Antacids decrease stomach acidity and improve levodopa absorption, while iron products bind levodopa and may reduce its absorption. Levodopa absorption requires active transport by a large neutral amino acid transporter protein (see Figure 33–2). Amino acids in food compete for this transport mechanism. Thus, in advanced disease, avoidance of protein-rich meals in relationship to levodopa doses may be helpful.1,28,29,33

Controlled-release (CR) formulations act longer than immediate-release tablets but are absorbed slower. This result in a delayed onset (45–60 minutes) compared with the standard formulation (15–30 minutes); thus patients may require immediate-release tablets or even a liquid formulation when they want a quicker onset of effect, such as with the first morning dose. Because of reduced bioavailability, the total daily dose of CR preparations should be increased by 30%. In early 2015, an extended-release formulation of levodopa (Rytary) was approved. Doses are not directly interchangeable with other levodopa preparations. Its ideal place in therapy is yet to be determined.1,2,28,33

Converting patients from oral formulations to enteral or duodenal levodopa administration reduces motor fluctuations and improves UPDRS scores. The levodopa/carbidopa combination can be administered directly to the duodenum via a small tube. This formulation is marketed under the trade name Duodopa in Europe and Canada, but it is unavailable in the United States. It is reserved for advanced PD with severe motor fluctuations.46

Levodopa is usually administered as a combination product with carbidopa, a dopa-decarboxylase inhibitor, which decreases the peripheral conversion of levodopa to dopamine. This allows for lower levodopa doses and minimizes levodopa peripheral side effects, eg, nausea, vomiting, anorexia, and hypotension. Carbidopa does not cross the blood–brain barrier and does not interfere with levodopa conversion in the brain. Generally 75 to 100 mg daily of carbidopa is required to adequately block peripheral dopa-decarboxylase. Higher doses of carbidopa may reduce nausea when initiating levodopa.1,28,29,33
Initial levodopa side effects include orthostatic hypotension, dizziness, anorexia, nausea, vomiting, and discoloration of urine/sweat. Most of these effects can be minimized by taking levodopa with food and by slowly titrating the dose. Side effects that develop later in therapy include dyskinesias, sleep attacks, impulse control disorders, and psychiatric effects (confusion, hallucinations, nightmares, and altered behavior). Dyskinesias caused by adding other PD drugs to levodopa may be improved by decreasing the levodopa dose.\(^2,28,29,33\)

Because Levodopa is short acting, it has a greater risk of causing end of dose wearing off periods that require medication adjustments. Patients with severe dyskinesias and off periods may achieve more constant blood concentrations (lower peak and higher trough concentrations) with a liquid formulation of levodopa with carbidopa compounded from tablets. This may allow for more precise dosing and improvements in motor symptoms and complications.\(^2,8,20,33,46\)

**Catechol–O–Methyltransferase (COMT) Inhibitors**

Inhibitors of COMT, an enzyme that catalyzes levodopa to 3-omethyldopa, are added to levodopa/carbidopa to increase levodopa concentrations, extend its half-life, and decrease wearing off time. Using the COMT inhibitors entacapone or tolcapone may allow for a decrease in daily levodopa dose while increasing on time by 1 to 2 hours. Side effects include diarrhea (worse with tolcapone), nausea, vomiting, anorexia, dyskinesias, urine discoloration, daytime sleepiness, sleep attacks, orthostatic hypotension, and hallucinations. Dyskinesias should improve with a decrease in the levodopa dose.\(^2,8,20,33\)

Tolcapone should be used only in patients who do not tolerate or respond to entacapone due to its hepatic safety profile. Serum liver function tests should be monitored at baseline, every 2 to 4 weeks for 6 months, and then periodically for the remainder of therapy. Patients who fail to show symptomatic benefit after 3 weeks should discontinue tolcapone.\(^2,8,20,33\)

**Herbs and Supplements**

There is very little support for using creatine, gingko, ginseng, green tea, ginger, yohimbine, or St. John’s wort in patients with PD.

Patients should eat a balanced diet and consider a multivitamin with minerals, but supplementation with specific vitamins is generally unnecessary.\(^9\)

**TREATMENT OF NONMOTOR SYMPTOMS**

**KEY CONCEPT** Treatment of nonmotor symptoms should be based on whether they are exacerbated by an off state or might be related to other neurotransmitter dysfunction.

The treatment of nonmotor symptoms, such as psychological conditions, sleep disorders, and autonomic dysfunction, should include both pharmacologic and nonpharmacologic approaches. Patients should be supported to maintain ADLs, a positive self-image, family communication, and a safe environment.

**Psychological Symptoms**

Psychological symptoms and psychosis are potential problems in PD patients. When psychological changes are suspected, potential causes to rule out include infections, metabolic changes, electrolyte disturbances, or toxic exposures.

**Depression**

Depression is extremely common in patients with PD, affecting 40% or more of patients, and it often precedes the disease. Brain catecholamine changes and serotonin dysregulation contribute to depression associated with PD. Although evidence supports efficacy of tricyclic antidepressants in this population, their adverse effect profile limits their use. Alternatively, selective serotonin reuptake inhibitors may be considered because of their increased tolerability. Pramipexole may also improve depression.\(^19\) Antidepressants are also useful for the treatment of anxiety disorders. Because off periods can both precipitate anxiety and worsen depression, therapy should be adjusted to maximize on periods.\(^2,7,8,15,18\)

**Dementia**

Dementia occurs in approximately 80% of patients with PD 20 years after diagnosis, and decreased cholinergic neurotransmission is implicated. Cholinesterase inhibitors may be effective, but the efficacy of memantine is unclear.\(^2,15,18–20,38\)

**Psychosis**

First treat any underlying medical causes for psychosis (infections, electrolyte disturbances). Then gradually decrease and stop low-efficacy PD medications. Antipsychotics should be used cautiously in patients with PD because they may worsen motor symptoms and may increase the risk of death in patients with concurrent dementia. However, if reducing PD medication compromises motor control or does not improve psychosis, low-dose quetiapine (12.5–200 mg) at bedtime may improve psychosis and is preferred with close monitoring for long-term metabolic side effects. Clozapine is also recommended but requires stringent monitoring (see Chapter 37).\(^2,15,16–20\)

**Sleep Problems**

Sleep problems and fatigue are common in PD and may be due to medications, uncontrolled PD symptoms, or other causes such as nocturia, sleep attacks during the day, depression, RBD, or restless legs syndrome (RLS). Instruction on good sleep hygiene, improvement in nighttime PD symptoms, or cognitive behavioral therapy may help.\(^2,15,16\)

The rotigotine patch may improve early morning motor function and overall quality of sleep.\(^37\)

Amantadine and selegiline may worsen insomnia, selegiline and tricyclic antidepressants may worsen REM sleep, and some antidepressants and antipsychotics may worsen RLS. Melatonin may improve patient perception of sleep, but this has not been fully validated. Levodopa/carbidopa reduces nighttime periodic leg movements; while data regarding nonergot dopamine agonists are lacking in patients with PD. When iron is used for RLS, it may decrease the absorption of levodopa and increase constipation. A nighttime dose of a COMT inhibitor may improve RLS.\(^2,4,16\)

**Autonomic and Other Problems**

Drooling may be accompanied by speech problems and dysphagia. Ach, botulinum toxin injections, and sublingual atropine can decrease drooling. Nausea improves if PD medications are taken with meals and with antiemetic therapy (eg, domperidone or trimethobenzamide).

Sexual dysfunction or urinary problems may require further evaluation. Adjustment of PD therapy to increase on time, removal of drugs that decrease sexual response, and pharmacologic therapy (eg, sildenafil) may improve sexual dysfunction. Studies of sexual dysfunction in women with PD are lacking.

Patients with urinary frequency may find a bedside urinal and a decrease in evening fluid intake helpful. Improvement in PD
symptom control can decrease urinary frequency, but worsening symptoms may require catheterization or pharmacologic measures (eg, oxybutynin, tolterodine, propantheline, imipramine, hyoscymamine, or nocturnal intranasal desmopressin).

Anticholinergic drugs can cause urinary retention and constipation. Constipation can be improved by increased fluid intake, a fiber-rich diet, probiotics, and physical activity. Stool softeners, osmotic or bulk-forming laxatives, glycerin suppositories, or enemas may help, while cathartic laxatives should be avoided.

Dyskinesia-related sweating may respond to PD therapy adjustment or β-blockers.

Treating orthostasis includes the removal of offending drugs (eg, tricyclic antidepressants, PD medications, alcohol, and antihypertensives) increasing carbidopa doses, increased salt or fluids to the diet, compression stockings, fludrocortisone, indomethacin, or midodrine. Droxidopa, a norepinephrine synthetic precursor, was recently approved for treating orthostatic hypotension associated with PD. 38

Seborrhea usually responds to over-the-counter dandruff shampoos or topical steroids. 2,6,10,17

### Treatment of Response Fluctuations

**KEY CONCEPT** As the disease progresses, most patients develop response fluctuations. Treatment is based on capitalizing on the pharmacokinetic and pharmacodynamic properties of PD medications.

Treatment includes adjusting or adding medications to maximize the patient’s on time, minimizing the time on with dyskinesia, and minimizing off time (Table 33–3). Use various dosage plans to minimize suboptimal or delayed peak levodopa concentrations by adding longer acting medications to minimize wearing-off periods, adding or adjusting medications to stop an unpredicted off period, and providing treatments that decrease freezing episodes. Treatment plans also involve adjusting or adding medications to decrease chorea, dystonia, diphasic dyskinesias, or akathisia. Patients should schedule activities when they are on. An extra dose of medication carried with them when they are away from home in case their medication wears off is also advisable. 2,7,11,14,15

### OUTCOME EVALUATION

**KEY CONCEPT** Patient monitoring involves a regular systematic evaluation of efficacy and adverse events, referral to appropriate specialists, and patient education. Evaluate the clinical outcomes of treatment over time by assessing the change in the UPDRS from baseline. Instruct patients to record daily the amount of on and off time to guide medication adjustment. Patients with PD have an increased risk for falls. Assess fall risk and implement appropriate safety measures to prevent falls. Scales assessing QOL, depression, anxiety, and sleep disorders are useful to track progression.

### Patient Encounter, Part 4: Second Follow-up Visit 3 Months Later

The patient comes in for a follow-up visit with no new complaints. At her last visit 3 months ago, ropinirole was removed, and her daily Sinemet dose was increased to cover the afternoon off period that had previously been treated with ropinirole. Since then she reports a similar level of functioning with minimal off time and no dyskinesias. She denies any auditory or visual hallucinations or vivid dreams. She denies feeling dizzy when standing and does not report any more falls. She has joined an exercise class at the senior center. She continues to have five to seven bowel movements per week.

**UPDRS 40 (on)**

**Meds:** Carbidopa/levodopa 25 mg/100 mg orally—two tablets at 7 AM, one tablet at 11:30 AM, one tablet at 4 PM, and one tablet at 9 PM; polyethylene glycol (MiraLAX) 17 g/scoop. One scoop in 4 to 8 oz (120–240 mL) of liquid, one to two times per week as needed for constipation.

If her psychosis had continued and was determined to be a nonmotor symptom of PD rather than an adverse effect of her dopaminergic therapy, what options might you consider?

If this patient’s dyskinesias in the morning continued despite removal of the dopamine agonist, what options might you consider?

Were therapeutic goals achieved in this patient after discontinuation of her dopamine agonist and adjustment of her carbidopa/levodopa?

How would you counsel a patient who has been on PD medications and is initiating an atypical antipsychotic such as quetiapine?

If a patient was unable to speak due to disease progression, what would be the advantages and disadvantages of having a significant other communicate for the patient?

### Patient Encounter, Part 3: First Follow-up Visit 3 Months Later

The patient returns for a follow-up visit 3 months after adjustments were made to her therapy. At her last appointment, ropinirole was added and prochlorperazine was removed. Since then, she reports improvement in her ability to cook and can go for longer walks. She feels that she has less tremor and stiffness throughout the day with no off periods. However, about an hour after she takes her morning dose of carbidopa/levodopa with ropinirole, her husband describes movements consistent with chorea. Additionally, her husband reports that she sometimes sees faces in the shadows at night. She also reports feeling dizzy and lightheaded when standing quickly from sitting in a chair and has fallen. She is more physically active with improved PD symptoms. She is taking polyethylene glycol one time per week with five to seven bowel movements per week. Her nighttime urgency to urinate is decreased with a reduction in fluids and her nausea has improved with a change to carbidopa/levodopa 25 mg/100 mg tablets.

**UPDRS 40 (on)**

Create a problem list and provide an assessment of each problem.

Considering the goals of therapy, treatment options, and your assessment of each of the problems, create a care plan for each problem.

From Refs. 2, 12, 21, and 22.
Patient Care Process

**Patient Assessment:**
- Based on reported symptoms and physical exam, document type of symptoms, frequency, and exacerbating factors (clinical presentation table).
- Review diagnostic data and determine if symptoms are adequately controlled or if PD treatment-related complications exist. How does the current UPDRS score compare to previous measurements? Is there evidence of motor fluctuations or dyskinesias?
- Obtain a medication history. What treatments have been helpful? Is the patient taking any medications that may worsen PD symptoms?

**Therapy Evaluation:**
- Determine if therapy for motor symptoms of PD are maximizing on time and should be maintained or require adjustment.
- Evaluate for polypharmacy. Is this necessary or can medications be removed?
- Review nonmotor symptoms and evaluate if they are adequately treated. Have QOL measures improved?
- Assess the complete PD pharmacologic profile for efficacy, drug or diet interactions, adverse drug reactions, and adherence.

**Care Plan Development:**
- Educate the patient about lifestyle modifications that will improve symptoms and sustain independence.
- Recommend a therapeutic regimen that is easy for the patient to follow.
- Provide instruction on how to use medications, and allow the patient to adjust medications for fluctuations in response.
- Refer the patient and family members to further information such as books and websites (eg, http://www.apdaparkinson.org; http://www.parkinson.org). Provide information concerning local PD support groups when available.

**Follow-Up Evaluation**
- Assess the patient’s symptoms and disease progression through the UPDRS and QOL measures periodically. This interval will vary depending on symptom control, stage of illness, and changes to therapy.
- Follow up at least every 6 to 12 months (or earlier) and determine when symptoms are controlled, if the patient is experiencing any drug interactions or adverse reactions, and provide patient education on medications and nonpharmacologic options as appropriate.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify characteristics of the types of pain: nociceptive, inflammatory, neuropathic, and functional.
2. Explain the mechanisms involved in pain transmission.
4. Recommend an appropriate choice of analgesic, dose, and monitoring plan for a patient based on type and severity of pain and other patient-specific parameters.
5. Perform calculations involving equianalgesic doses, conversion of one opioid to another, rescue doses, and conversion to a continuous infusion.
6. Educate patients and caregivers about effective pain management, dealing with chronic pain, and the use of nonpharmacologic measures.

INTRODUCTION

Pain is defined by the International Association for the Study of Pain (IASP) as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage." Pain is an unpleasant subjective experience that is the net effect of a complex interaction of the ascending and descending neurons involving biochemical, physiologic, psychological, and neocortical processes. Pain can affect all areas of a person's life including sleep, thought, emotion, and activities of daily living. Because there are no reliable objective markers for pain, the patient is the only person who can describe the intensity and quality of their pain.

Pain is the most common symptom prompting patients to seek medical attention and is reported by more than 80% of individuals who visit their primary care provider. Despite the frequency of pain symptoms, individuals often do not obtain satisfactory relief of pain. This has led to initiatives in health care to make pain the fifth vital sign, thus making pain assessment equal in importance to obtaining a patient's temperature, pulse, blood pressure, and respiratory rate.

EPIDEMIOLOGY AND ETIOLOGY

Prevalence of Pain

Most people experience pain at some time in their lives, and pain is a symptom of a variety of diseases. Thus identifying the exact prevalence of pain is a difficult task. According to the American Pain Foundation, more than 76 million people in the United States suffer from chronic pain, and an additional 25 million experience acute pain from injury or surgery.

Prevalence rates for a variety of different types of pain have been described. Approximately one-fourth of US adults reported having low back pain lasting at least 1 day in the past 3 months. Migraine affects more than 28 million Americans, and 78% of Americans experience a tension headache during their lifetime. Pain resulting from fibromyalgia affects 10 million Americans. Pain ranges in prevalence from 14% to 100% among cancer patients. The prevalence of neuropathic pain is unknown because of the lack of epidemiologic studies. Current estimates suggest that approximately 1.5% of the population in the United States might be affected by neuropathic pain. Approximately 25% to 50% of all pain clinic visits are related to neuropathic pain. Central neuropathic pain is estimated to occur in 2% to 8% of all stroke patients.

The elderly, defined as people 65 years and older, bear a significant burden of pain, and pain continues to be underrecognized and undertreated in this population. The prevalence of pain in people older than 60 years is twice that in those younger than 60 years. Studies suggest that 25% to 50% of community-dwelling elderly suffer pain. Pain is quite common among nursing home residents. It is estimated that pain in 45% to 80% of nursing home patients contributes to functional impairment and a decreased quality of life.

The financial impact of pain is considered to be significant. The American Productivity Audit of the US workforce, conducted from 2001 to 2002, revealed that the cost of lost productivity due to arthritis, back pain, headache, and other musculoskeletal pain was approximately $61.2 billion per year.

Undertreatment of Pain

Despite the growing emphasis on pain management, pain often remains undertreated and continues to be a problem in hospitals, long-term care facilities, and the community. In one series of reports, 50% of seriously ill hospitalized patients reported pain; however, 15% were dissatisfied with pain control, and some remained in pain after hospitalization.
Misconceptions about pain management, both from patients and health care providers, are among the most common causes of analgesic failure. Concerns about opiate misuse, abuse, and diversion also contribute to less than optimal pain management and cause providers to exercise caution when prescribing opiates for pain. Misunderstandings about the terms addiction, physical dependence, tolerance, and pseudoaddiction are additional obstacles to optimal pain management.

Patients might present barriers to pain management by not reporting pain symptoms because of fear of becoming addicted or because of cultural beliefs. Elderly patients might not report pain for a variety of reasons including belief that pain is something they must live with, fear of consequences (eg, hospitalization, loss of independence), or fear that the pain might be forecasting impending illness, inability to understand terminology used by health care providers, or a belief that showing pain is unacceptable behavior.

PATHOPHYSIOLOGY

Types of Pain

Several distinct types of pain have been described, for example, nociceptive, inflammatory, neuropathic, and functional. Nociceptive pain is a transient pain in response to a noxious stimulus at nociceptors that are located in cutaneous tissue, bone, muscle, connective tissue, vessels, and viscera. Nociceptors are classified as thermal, chemical, or mechanical. The nociceptive system extends from the receptors in the periphery to the spinal cord, brainstem, to the cerebral cortex where pain sensation is perceived. This system is a key physiologic function that prevents further tissue damage due to the body’s autonomic withdrawal reflex. When tissue damage occurs despite the nociceptive defense system, inflammatory pain ensues. The body now changes focus from protecting against painful stimuli to protecting the injured tissue. The inflammatory response contributes to pain hypersensitivity that serves to prevent contact or movement of the injured part until healing is complete, thus reducing further damage.

Neuropathic pain is defined as spontaneous pain and hypersensitivity to pain associated with damage to or pathologic changes in the peripheral nervous system as in painful diabetic peripheral neuropathy (DPN), adult immune deficiency syndrome (AIDS), polyneuropathy, postherpetic neuralgia (PHN), or in the central nervous system (CNS), which occurs with spinal cord injury, multiple sclerosis, and stroke. Functional pain, a relatively newer concept, is pain sensitivity due to an abnormal processing or functioning of the CNS in response to normal stimuli. Several conditions considered to have this abnormal sensitivity or hyperresponsiveness include fibromyalgia and irritable bowel syndrome.

Mechanisms of Pain

Pain Transmission

The mechanisms of nociceptive pain are well defined and provide a foundation for the understanding of other types of pain. Following nociceptor stimulation, tissue injury causes the release of substances (bradykinin, serotonin, potassium, histamine, prostaglandins, and substance P) that might further sensitize and/or activate nociceptors. Nociceptor activation produces action potentials (transduction) that are transmitted along myelinated Aδ-fibers and unmyelinated C-fibers to the spinal cord. The Aδ-fibers are responsible for first, fast, sharp pain and release excitatory amino acids that activate α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors in the dorsal horn. The C-fibers produce second pain, which is described as dull, aching, burning, and diffuse. These nerve fibers synapse in the dorsal horn of the spinal cord, where several neurotransmitters are released including glutamate, substance P, and calcitonin gene-related peptide. Transmission of pain signals continues along the spinal cord to the thalamus, which serves as the pain relay center, and eventually to the cortical regions of the brain where pain is perceived.

Pain Modulation

Modulation of pain (inhibition of nociceptive impulses) can occur by a number of processes. Based on the gate-control theory, pain modulation might occur at the level of the dorsal horn. Because the brain can process only a limited number of signals at one time, other sensory stimuli at nociceptors might alter pain perception. This theory supports the effectiveness of counterirritants and transcutaneous electrical nerve stimulation (TENS) in pain management. Pain modulation can occur through several other complex processes. The endogenous opiate system consists of endorphins (enkephalins, dynorphins, and β-endorphins) that interact with μ-, δ-, and κ-receptors throughout the CNS to inhibit pain impulses and alter perception. The CNS also includes inhibitory descending pathways from the brain that can attenuate pain transmission in the dorsal horn. Neurotransmitters involved in this descending system include endogenous opioids, serotonin, norepinephrine, γ-aminobutyric acid (GABA), and neurotensin. The perception of pain involves not only nociceptive stimulation but physiologic and emotional input that contributes to the perception of pain. Consequently, cognitive behavioral treatments such as distraction, relaxation, and guided imagery can reduce pain perception by altering pain processing in the cortex.

Peripheral Sensitization, Central Sensitization, and Windup

Under normal conditions, a balance generally exists between excitatory and inhibitory neurotransmission. Changes in this balance can occur both peripherally and centrally, resulting in exaggerated responses and sensitization, such as that observed in inflammatory, neuropathic, or functional chronic pain. Pain in these settings might occur spontaneously without any stimulus or might be evoked by a stimulus. Evoked pain might arise from a stimulus that normally does not cause pain (allodynia) such as a light touch in neuropathic pain. Hyperalgesia, an exaggerated and/or prolonged pain response to a stimulus that normally causes pain, can also occur as a result of increased sensitivity in the CNS.

During normal pain transmission, the AMPA receptors are activated, but the N-methyl-D-aspartate (NMDA) receptor is blocked by magnesium. Repeated nerve depolarization causes release of the magnesium block, allowing the influx of calcium and sodium, and results in excessive excitability and amplification of signals. Continued input from C-fibers and subsequent increases in substance P and glutamate causes the activation of the NMDA receptor, a process referred to as windup. Windup increases the number and responsiveness of neurons in the dorsal horn irrespective of the input from the periphery. Recruitment of neurons not normally involved in pain transmission or spread occurs, leading to allodynia, hyperalgesia, and spread to uninjured tissues. The windup phenomenon supports the observation that untreated acute pain can lead to chronic pain and the belief that pain processes are plastic and not static.
CLINICAL PRESENTATION AND DIAGNOSIS

Classification of Pain

Pain has always been described as a symptom. However, recent advances in the understanding of neural mechanisms have demonstrated that unrelieved pain might lead to changes in the nervous system known as neural plasticity. Because these changes reflect a process that influences a physiologic response, pain, particularly chronic pain, might be considered a disease unto itself.

Pain can be divided into two broad categories: acute and chronic pain. Acute pain is also referred to as adaptive pain because it serves to protect the individual from further injury or promote healing. Chronic pain has been called maladaptive, a pathologic function of the nervous system or pain as a disease.

► Acute Pain

Acute pain is pain that occurs as a result of injury or surgery and is usually self-limited, subsiding when the injury heals. Untreated acute pain can produce physiologic symptoms including tachypnea, tachycardia, and increased sympathetic nervous system activity, such as pallor, diaphoresis, and pupil dilation. Furthermore, poorly treated pain can cause psychological stress and compromise the immune system due to the release of endogenous corticosteroids. Somatic acute pain arises from injury to skin, bone, joint, muscle, and connective tissue, and it is generally localized to the site of injury. Visceral pain involves injury to nerves on internal organs (e.g., intestines, liver) and can present as diffuse, poorly differentiated, and often referred pain. Acute pain should be treated aggressively, even before the diagnosis is established, except in conditions of head or abdominal injury where pain might assist in the differential diagnosis.

► Chronic Pain

Chronic pain persists beyond the expected normal time for healing and serves no useful physiologic purpose. Chronic pain might be nociceptive, inflammatory, neuropathic, or functional in origin; however, all forms share some common characteristics. Chronic pain can be intermittent or persistent, or both. Physiologic responses observed in acute pain are often absent in chronic pain; however, other symptoms might predominate. The four main effects of chronic pain include (a) effects on the physical function, (b) psychological changes, (c) social consequences, and (d) societal consequences. Effects of chronic pain on physical function include impaired activities of daily living and sleep disturbances. Psychological components of chronic pain might include depression, anxiety, anger, and loss of self-esteem. As a result of physical and psychological changes, social consequences might ensue, such as changes in relationships with friends and family, intimacy, and isolation. Management of chronic pain should be multimodal and might involve cognitive interventions, physical manipulations, pharmacologic agents, surgical intervention, and regional or spinal anesthetics.

Chronic Malignant Pain Chronic malignant pain is associated with a progressive disease that is usually life threatening such as cancer, AIDS, progressive neurologic diseases, end-stage organ failure, and dementia. The goal is pain alleviation and prevention, often through a systematic and stepwise approach. Tolerance, dependence, and addiction are often not a concern due to the terminal nature of the illness.

Chronic Nonmalignant Pain Pain not associated with a life-threatening disease and lasting more than 6 months beyond the healing period is referred to as chronic nonmalignant pain. Pain associated with low back pain, osteoarthritis, previous bone fractures, peripheral vascular disease, genitourinary infection, rheumatoid arthritis, and coronary heart disease is considered nonmalignant. The numerous causes of this type of chronic pain make treatment complex and involves a multidisciplinary approach. Treatment is initially conservative but might involve the use of more potent analgesics including opiates in psychologically healthy patients.

Neuropathic Pain Neuropathic pain is considered to be a type of chronic nonmalignant pain involving disease of the central and peripheral nervous systems. Neuropathic pain might be broadly categorized as peripheral or central in nature. Examples of neuropathic pain include PHN, which is pain associated with acute herpetic neuralgia or an acute shingles outbreak. Peripheral or polynuropathic pain is associated with the distal polyneuropathies of diabetes, human immunodeficiency virus (HIV), and chemotherapeutic agents. Types of central pain include central stroke pain, trigeminal neuralgia, and a complex of syndromes known as complex regional pain syndrome (CRPS). CRPS includes both reflex sympathetic dystrophy and causalgia, both of which are neuropathic pain associated with abnormal functioning of the autonomic nervous system.

The symptoms of neuropathic pain are characterized as tingling, burning, shooting, stabbing, electric shock–like quality, or radiating pain. The patient might describe either a constant dull throbbing or burning pain, or an intermittent pain that is stabbing or shooting. Damage to the peripheral nerves might frequently be referred to the body region innervated by those nerves.

Pain Assessment

Effective pain management begins with a thorough and accurate assessment of the patient. Even though pain is a common presenting complaint, lack of regular assessment and reassessment of pain remains a problem and contributes to the undertreatment of pain.
Pain Assessment Guidelines/Regulations for Specific Practice Settings

Screening for pain should be a part of a routine assessment, which has led several organizations such as the Veterans Health Administration (VHA) and the American Pain Society (APS) to declare pain as the fifth vital sign. Many states have adopted a bill of rights for patients in pain. In 2001, the Joint Commission on Accreditation of Health Care Organizations (JCAHO) incorporated pain as the fifth vital sign in its accreditation standards. According to the JCAHO, patients have a right to appropriate assessment and management of their pain and education regarding their pain. Following initial assessment of pain, reassessment should be done as needed based on medication choice and the clinical situation.

Methods of Pain Assessment

A patient-oriented approach to pain is essential, and methods do not differ greatly from those used in other medical conditions. A comprehensive history (medical, family, and psychological) and physical are necessary to evaluate underlying disease processes for the source of pain and other factors contributing to the pain. A thorough assessment of the characteristics of the pain should be completed, including questions about the pain (onset, duration, location, quality, severity, and intensity), pain relief efforts, and efficacy and side effects of current and past treatments for pain. A common mnemonic for pain assessment is PQRST (Palliative/prefacilitating, Quality, Radiation, Severity, and Time). Some clinicians have suggested the addition of U (“you”) to this mnemonic.

During the pain interview, the impact of the pain on the patient’s functional status, behavior, and psychological states should also be assessed. Evaluation of psychological status is especially important in patients with chronic pain because depression and other affective disorders might be common comorbid conditions. A history of drug and alcohol use should be elicited due to the potential for addiction in patients who take opiates or other pain medications with a potential for abuse. Other conditions, such as renal or hepatic dysfunction, diabetes, and conditions that affect bowel function, can influence therapy choices and goals. A discussion of the patient’s expectations and goals with respect to pain management (level of pain relief, functional status, and quality of life) should also be part of any pain interview.

Pain Assessment Tools

Pain, particularly acute pain, might be accompanied by physiologic signs and symptoms, but there are no reliable objective markers for pain. Many tools have been designed for assessing the severity of pain including rating scales and multidimensional pain assessment tools.

Rating scales provide a simple way to classify the intensity of pain, and they should be selected based on the patient’s ability to communicate (Figure 34–1). Numeric scales are widely used and ask patients to rate their pain on a scale of 0 to 10, with 0 indicating no pain and 10 being the worst pain possible. Using this type of scale, 1 to 3 is considered mild pain, 4 to 6 is moderate pain, and 7 to 10 is severe pain. The visual analog scale (VAS) is similar to the numerical scale in that it requires patients to place a mark on a 10-cm line where one end is no pain, and the worst possible pain is on the other end. For patients who have difficulty assigning a number to their pain, a categorical scale might be an option to communicate the intensity of the pain experience. Examples of this include a simple descriptive list of words and the Wong–Baker FACES of Pain Rating Scale.

Multidimensional assessment tools obtain information about the pain and impact on quality of life, but they are often more time-consuming to complete. Examples of these types of tools include the Initial Pain Assessment Tool, Brief Pain Inventory, McGill Pain Questionnaire, the Neuropathic Pain Scale, and the Oswestry Disability Index.

Pain Assessment in Challenging Populations

Children Pain interviews can be conducted with children as young as 3 or 4 years of age; however, communication might be limited by vocabulary. Terms familiar to children such as hurt, owie, or boo boo might be used to describe pain. The VAS is best used with children older than 7 years. Other scales based on numbers of objects (eg, poker chips), increasing color intensity, or faces of pain might be helpful for children between 4 and 7 years of age. In children younger than 3 to 4 years, behavioral or physiologic measures, such as pulse or respiratory rate, might be more appropriate. Pain assessment in newborns and infants relies on behavioral observation for such clues as vocalizations (crying and fussing), facial expressions, body movements (flailing of limbs and pulling legs in), withdrawal, and change in eating and sleeping habits. Preschool children experiencing pain might become clingy, lose motor and verbal skills, and start to deny pain because treatment might be linked to discomfort or punishment. School-age children might exhibit aggressiveness, nightmares, anxiety, and withdrawal when in pain; adolescents might respond to pain with oppositional behavior and depression.

Elderly Most of the previously discussed pain scales can be used in older persons who are cognitively intact or with mild dementia. The pain thermometer and FACES of pain have been studied in older persons. In persons with moderate to severe dementia or those who are nonverbal, observation of pain behaviors, such as guarding or grimacing, provides an alternative for pain assessment. The Pain Assessment in Advanced Dementia (PAINAD)
tool might be used to quantify signs of pain and involves observing the older adult for 15 minutes for breathing, negative vocalizations, facial expression, body language, and consolability. Regardless of which pain assessment tool is used, the practitioner should first determine if the patient understands the concept of the scale to ensure reliability of the instrument.

**TREATMENT**

**Desired Outcomes**

Prevention, reduction, and/or elimination of pain are important goals for the treatment of acute pain. With chronic pain, elimination of pain might not be possible, and goals might focus on improvement or maintenance of functional capacity and quality of life.

**General Approach to Treatment**

**KEY CONCEPT** Effective treatment involves an evaluation of the cause, duration, and intensity of the pain, and selection of an appropriate treatment modality for the pain situation. Depending on the type of pain, treatment might involve pharmacologic and nonpharmacologic therapy or both. General principles for the pharmacologic management of pain are listed in the section “Patient Care Process.” Two common approaches to the selection of treatment are based on severity of pain and the mechanism responsible for the pain (Figure 34–2). Clinical practice guidelines for pain management are available from the APS, the Agency for Healthcare Research and Quality (AHRQ), the American Geriatrics Society (AGS), and the American Society of Anesthesiologists (ASA).

**Selection of Agent Based on Severity of Pain**

**KEY CONCEPT** Whenever possible, the least potent oral analgesic should be selected. Guidelines for the selection of therapeutic agents based on pain intensity are derived from the World Health Organization (WHO) analgesic ladder for the management of cancer pain (Table 34–1). Mild to moderate pain is generally treated with nonopioid analgesics. Combinations of medium-potency opioids and acetaminophen (APAP) or nonsteroidal anti-inflammatory drugs (NSAIDs) are often used for moderate pain. Potent opioids are recommended for severe pain. Throughout this progression, adjuvant medications are added, as needed, to manage side effects and to augment analgesia. While these guidelines can be useful for initial therapy, the clinical situation (type of pain), cost, pharmacokinetic profile of available drugs, and patient-specific factors (age, concomitant illnesses, etc.) need to be considered.

---

**FIGURE 34–2.** Pain algorithm. (AED, antiepileptic drugs; APAP, acetaminophen; MS, morphine sulfate; NSAIDs, nonsteroidal anti-inflammatory drugs; SNRI, serotonin norepinephrine reuptake inhibitors; SSRI, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressants.)
Mechanistic Approach to Therapy

Current analgesic therapy is aimed at controlling or blunting pain symptoms. However, diverse mechanisms contributing to the various types of pain continue to be further elucidated. An understanding of these new mechanisms of pain transmission might lead to improvement in pain management as pharmacologic management of pain becomes more mechanism specific. Use of NSAIDs for inflammatory types of pain is an example of a mechanistic approach. Because several mechanisms of pain often coexist, a polypharmacy approach seems rational to target each mechanism.

Nonpharmacologic Therapy

Nonpharmacologic therapies (psychological interventions and physical therapy) might be used in both acute and chronic pain. Psychological interventions can reduce pain as well as the anxiety, depression, fear, and anger associated with pain. Psychological interventions helpful in management of acute pain are imagery (picturing oneself in a safe, peaceful place) and distraction (listening to music or focusing on breathing). Chronic pain patients might benefit from relaxation, biofeedback, cognitive behavioral therapy, psychotherapy, support groups, and spiritual counseling.

Physical therapy is an essential part of many types of pain situations. Treatment modalities include heat, cold, water, ultrasound therapy, TENS, massage, and therapeutic exercise. Heat and cold therapy are utilized in a variety of musculoskeletal conditions (muscle spasms, low back pain, fibromyalgia, sprains, and strains).

Pharmacologic Therapy

Nonopioid Analgesics

Acetaminophen APAP, an analgesic and antipyretic, is often selected as initial therapy for mild to moderate pain and is considered first line in several pain situations such as low back pain and osteoarthritis. Mechanistically, APAP is believed to inhibit prostaglandin synthesis in the CNS and block pain impulses in the periphery. APAP is well tolerated at usual doses and has few clinically significant drug interactions except causing increased hypoprothrombinemic response to warfarin in patients receiving APAP doses of more than 2000 mg/day. The maximum recommended dose for patients with normal renal and hepatic function is 4000 mg/day. Hepatotoxicity has been reported with excessive use and overdose, and the risk of this adverse effect increases in those with hepatitis or chronic alcohol use, as well as those who binge drink or are in a fasting state. Due to concerns of unintentional overuse and hepatotoxicity, the FDA requires warning labels on OTC APAP products and limited the APAP component of narcotic analgesic combination to 325 mg per dosing unit. Regular chronic use of APAP has been associated with chronic renal failure, but reports are conflicting. For these reasons, the maximum dose should be reduced by 50% to 75% in patients with renal dysfunction or hepatic disease and in those who engage in excessive alcohol use.

Aspirin and Other Salicylates Aspirin, nonacetylated salicylates, and other NSAIDs have analgesic, antipyretic, and anti-inflammatory actions. These agents inhibit cyclooxygenase (COX-1 and COX-2) enzymes, thereby preventing prostaglandin synthesis, which results in reduced nociceptor sensitization and an increased pain threshold.

Aspirin is effective for mild to moderate pain; however, the risk of gastrointestinal (GI) irritation and bleeding limits frequent use of this drug for pain management. Direct effects of aspirin on the GI mucosa and irreversible platelet inhibition contribute to this risk, which can occur even at low doses. Hypersensitivity reactions are also possible and might occur in 25% of patients with coexisting asthma, nasal polyps, or chronic urticaria. Of additional concern is the potential for cross-sensitivity of other NSAIDs in this group of patients. Nonacetylated salicylates (choline magnesium salicylate and sodium salicylate) have a reduced risk of GI effects and platelet inhibition and might be used in aspirin-sensitive patients.

Nonsteroidal Anti-inflammatory Drugs NSAIDs are the preferred agents for mild to moderate pain in situations that are mediated by prostaglandins (rheumatoid arthritis, menstrual cramps, and postsurgical pain) and in the management of pain from bony metastasis, but they are of minimal use in neuropathic pain.

Data from Refs. 35, 36, and 39.
NSAIDs provide analgesia equal to or better than that of aspirin or APAP combined with codeine, and they are very effective for inflammatory pain and pain associated with bone metastasis. These agents are classified by their chemical structures (fenamates, acetic acids, propionic acids, pyranocarboxylic acids, pyrrolizine carboxylic acids, and COX-2 inhibitors). Although only some members of this class have approval for treatment of pain, it is likely that all of them have similar analgesic effects. All members of this class appear to be equally effective, but there is great intrapatient variability in response. After an adequate trial of 2 to 3 weeks with a particular oral agent, it is reasonable to switch to another member of the class. Ketorolac and ibuprofen are available in parenteral and oral dosage forms; unlike other NSAIDs, ketorolac’s duration of use is limited to 5 days. NSAIDs demonstrate a flat-dose response curve, with higher doses producing no greater efficacy than moderate doses but resulting in an increased incidence of adverse effects (GI irritation, hepatic dysfunction, renal insufficiency, platelet inhibition, sodium retention, and CNS dysfunction).

Patients at increased risk of NSAID-induced GI adverse effects (e.g., dyspepsia, peptic ulcer formation, and bleeding) include the elderly, those with peptic ulcer disease, coagulopathy, and patients receiving high doses of concurrent corticosteroids. Nephrotoxicity is more common in the elderly, patients with creatinine clearance values less than 50 mL/min (0.84 mL/s), and those with volume depletion or on diuretic therapy. NSAIDs should be used with caution in patients with reduced cardiac output due to sodium retention and in patients receiving antihypertensives, warfarin, and lithium.

NSAIDs are classified as nonselective (they inhibit COX-1 and COX-2) or selective (inhibit only COX-2) based on degree of COX inhibition. COX-2 inhibition is responsible for anti-inflammatory effects, whereas COX-1 inhibition contributes to increased GI and renal toxicity associated with nonselective agents. Because the antiplatelet effect of nonselective NSAIDs is reversible, concurrent use might reduce the cardioprotective effect of aspirin due to competitive inhibition of COX-1. For this reason, administration of aspirin prior to the NSAID is recommended. A boxed warning highlighting the potential for increased risk of cardiovascular events and GI bleeding is now required for all prescription nonselective NSAIDs and celecoxib. Stronger warnings about these adverse events are also required on nonprescription NSAIDs. When a NSAID is needed in a patient with cardiovascular risk, the benefits of therapy must outweigh the risks, and the lowest effective dose of the NSAID is recommended.

### Opioid Analgesics

Opioids are considered the agents of choice for the treatment of severe acute pain and moderate to severe pain associated with cancer. For chronic pain, use of long-term opioids has increased dramatically, however, evidence on the benefits, risk of abuse, and potential harm of long-term use of opioids in chronic pain is limited. Opioids are classified by their activity at the receptor site, usual pain intensity treated, and duration of action (short acting versus long acting).

#### Selection and Dosing

The opioids exert their analgesic efficacy by stimulating opioid receptors (μ, κ, and δ) in the CNS. There is a wide variety of potencies among the opioids, with some used for moderate pain (codeine, hydrocodone, tramadol, and partial agonists) and others reserved for severe pain (morphine and hydromorphone). Pure agonists (morphine) bind to μ-receptors to produce analgesia that increases with dose without a ceiling effect. Pure agonists are divided into three chemical classes: phenanthrenes or morphine-like, phenyl piperidine or meperidine-like, and diphenyl hetpane or methadone-like. Partial agonists/antagonists (butorphanol, pentazocine, and nalbuphine) partially stimulate the μ-receptor and antagonize the κ-receptors. This activity results in reduced analgesic efficacy with a ceiling dose, reduced side effects at the μ-receptor, psychotomimetic side effects due to κ-receptor antagonism, and possible withdrawal symptoms in patients who are dependent on pure agonists.

- Selection of the agent and route depend on individual patient-related factors including severity of pain, individual perceptions, weight, age, opioid tolerance, and concomitant disease (renal or hepatic dysfunction). Because pure agonists are pharmacologically similar, choice of agent might be also guided by pharmacokinetic parameters and other drug characteristics. Hepatic impairment can decrease the metabolism of most opioids, particularly methadone, meperidine, and pentazocine. Furthermore, the clearance of meperidine and morphine and their metabolites is reduced in renal dysfunction.

Table 34–2 provides a summary of opiate options, but several drugs warrant further discussion. Normeperidine, the active metabolite of meperidine, can produce tremors, myoclonus, delirium, and seizures. Due to the potential for accumulation of normeperidine, meperidine should not be used in the elderly, those with renal impairment, in patients using patient-controlled analgesia (PCA) devices, or for more than 1 to 2 days of intermittent dosing. Methadone is unique among the opiates because it has several mechanisms (μ-agonist, NMDA-receptor antagonist, and inhibition of reuptake of serotonin and norepinephrine). The long-half of methadone (30 hours) permits extended dosing

<sup>a</sup>Transdermal: 100 mcg/hour = 2–4 mg/hour of IV morphine.

<sup>b</sup>Dosage calculations when converting from morphine to methadone are not linear. The equianalgesic dose of methadone will decrease progressively as the morphine equivalents increase (Table 34–4).

Data from Refs. 24, 39, 42, and 43.
intervals; however, the potential for accumulation with repeated dosing often results in challenging dose conversion and concerns for respiratory depression. Another safety concern with methadone involves risk of arrhythmia secondary to QT prolongation. Tramadol is a synthetic opioid with a dual mechanism of action (µ-agonist and inhibition of serotonin and norepinephrine reuptake) and efficacy and safety similar to that of equianalgesic doses of codeine plus APAP. Tramadol has been evaluated in several types of neuropathic pain and might have a role in the treatment of chronic pain. Tramadol is associated with an increased risk of seizures in patients with a seizure disorder, those at risk for seizures, and those taking medications that can lower the seizure threshold. Doses greater than 500 mg have also been associated with seizures. The use of tramadol with other serotonergic drugs (eg, selective serotonin reuptake inhibitors [SSRIs]) might precipitate serotonin syndrome. Although originally thought not to be habit forming, dependence can occur with tramadol.

About 70% of individuals will experience significant analgesia from 10 mg/70 kg of body weight of IV morphine or its equivalent.44 For severe pain in opiate-naïve patients, a usual starting dose is 5 to 10 mg of IV morphine every 4 hours. In the initial stages of severe pain, medication should be given around the clock. Rescue doses should be made available for breakthrough pain in doses equivalent to 10% to 20% of the total daily opioid requirement and administered every 2 to 6 hours if needed. Alternatively, one-sixth of the total daily dose or one-third of the 12-hourly dose might be used. Scheduled doses should be titrated based on the degree of pain. One method involves adjustment of the maintenance dose based on the total 24-hour rescue dose requirement. Alternatively, utilizing dose escalation, doses could be increased by 50% to 100% or 30% to 50% of the current dose, for those in severe and moderate pain, respectively. Once pain relief is achieved, and if treatment is necessary for more than a few days, conversion to a controlled-release or long-acting opioid should be made with an equal amount of agent. Several sustained-release products are available containing morphine, oxycodone, and fentanyl. Some clinicians will reduce the total daily dose of the long-acting dosage form by 25% when initiating a sustained-release product to reduce the likelihood of oversedation. The dose of a pure agonist is limited only by tolerability to side effects. Tolerance might develop to analgesic effects, necessitating increasing doses to achieve the same level of pain relief. Physical dependence will occur with the long-term use of opioids. However, addiction or psychological dependence is unlikely in legitimate pain patients unless there are predisposing risk factors. Pain patients who are undertreated might appear to be drug seeking (pseudoaddiction); however, effective pain management resolves the behaviors. When opioids are used for chronic pain, use of informed consent for chronic opioid therapy, medication management agreements, or pain contracts might be appropriate to monitor the use (prescribing and dispensing) of controlled substances.

Opioids are administered by a variety of routes, including oral (tablet and liquid), sublingual, rectal, transdermal, transmucosal, IV, subcutaneous, and intraspinal. Although the oral and transdermal routes are most common, the method of administration is based on patient needs (severity of pain) and characteristics (swallowing difficulty and preference). Oral opioids have an onset of effect of 45 minutes, so IV or subcutaneous administration might be preferred if more rapid relief is desired. Intramuscular (IM) injections are not recommended because of pain at the injection site and wide fluctuations in drug absorption and peak plasma concentrations achieved. More invasive routes of administration such as PCA and intraspinal (epidural and intrathecal) are primarily used postoperatively but might also be used in refractory chronic pain situations. PCA delivers a self-administered dose via an infusion pump with a preprogrammed dose, minimum dosing interval, and a maximum hourly dose. Morphine, fentanyl, and hydromorphone are commonly administered via PCA pumps by the IV route but less frequently by the subcutaneous or epidural route.

Epidural analgesia is frequently used for lower extremity procedures and pain (eg, knee surgery, labor pain, and some abdominal procedures). Intermittent bolus or continuous infusion of preservative-free opioids (morphine, hydromorphone, or fentanyl) and local anesthetics (bupivacaine) might be used for epidural analgesia. Opiates given by this route might cause pruritus that is relieved by naloxone. Adverse effects including respiratory depression, hypotension, and urinary retention might occur. When epidural routes are used in narcotic-dependent patients, systemic analgesics must also be used to prevent withdrawal because the opioid is not absorbed and remains in the epidural space. Doses of opioids used in epidural analgesia are 10 times less than IV doses, and intrathecal doses are 10 times less than epidural doses (ie, 10 mg of IV morphine is equivalent to 1 mg epidural morphine and 0.1 mg of intrathecally administered morphine).38

Combination Analgesics Combinations of opioids and nonopioids often result in enhanced analgesia and lower dose of each. Combination analgesics are frequently used in moderate pain. However, in severe pain, the nonopioid component reaches maximum dosage, and thus the usefulness of nonopioids in this situation is limited. Additionally, the combination products are short acting and often not suitable for chronic therapy. Single agents offer greater dosing flexibility than combination products.

Opioid Allergy True narcotic allergies are rare and should not be confused with pruritus associated with opiate use. Cross-sensitivity between morphine-like, meperidine-like, and methadone-like agents is unlikely. Therefore, when an individual is allergic to one drug in a chemical class of opioids, it is reasonable to select an agent in another chemical class. For the purpose of drug selection in patients with allergies, mixed agonists/antagonists should be treated as morphine-like agents.

Tapering of Opioids Tapering of opioids might be necessary once the painful situation has resolved in patients receiving doses greater than 160 mg/day of oral morphine (or the equivalent) or in those with prolonged opioid use. In these situations, the dose should be reduced by 15% to 20% each day to avoid withdrawal symptoms.

Managing Opioid Side Effects and Drug Interactions Side effects common to all opioids include sedation, hallucinations, constipation, nausea and vomiting, urinary retention, myoclonus, and respiratory depression. Table 34–3 shows management strategies for side effects. The most frequent side effects are sedation, nausea, and constipation. Sedation and nausea are common when initiating therapy and when increasing doses. Tolerance to respiratory depression develops rapidly with repeated doses, and respiratory depression is rarely a clinically significant problem in pain patients even those with respiratory impairment. Constipation is a significant adverse effect to which tolerance does develop, and prophylaxis with stimulant laxatives (eg, senna or bisacodyl) and stool softeners such as docusate is recommended.

</table>

IM, intramuscular; po, orally; PR, per rectum.

Data from Refs. 25, 39, and 42.

Codeine, hydrocodone, morphine, methadone, and oxycodone are substrates of the cytochrome P450 (CYP) enzyme: CYP2D6. Inhibition of CYP2D6 results in decreased analgesia of codeine and hydrocodone due to decreased conversion to the active metabolites (eg, morphine and hydromorphone, respectively) and increased effects of morphine, methadone, and oxycodone. Methadone is also a substrate of CYP3A4, and its metabolism is increased by phenytoin and decreased by cimetidine. CNS depressants might potentiate the sedative effects of opiates.

**Opioid Rotation** Opioid rotation is the switch from one opioid to another to achieve a better balance between analgesia and treatment-limiting adverse effects. This practice is often used when escalating doses (greater than 1 g morphine/day) become ineffective. In some settings, opioid rotation is used routinely to prevent the development of analgesic tolerance.

**Equianalgesic Dosing of Opioid Analgesics** Conversion from one dosage form to another or from one opioid to another might be necessary in situations such as ineffective pain control, emergence of side effects, change in patient status, and in formulary restrictions. **Equianalgesic doses should be used when converting from one opioid to another.** Clinicians should be familiar with the equianalgesic dosing and conversion strategies to avoid analgesic failure. Opioid potency is compared using a reference standard of 10 mg parenteral morphine. Switching from one dosage form to another of the same opioid (ie, IV to oral) is relatively simple. The current total daily dose is calculated and the total of the new dosage form is determined using a ratio of the equianalgesic doses. This result is then adjusted based on the usual dosing frequency of the new form. When converting to a sustained-release form of the same opioid, the oral dosage may be reduced by 25% to avoid initial sedation; however, the specific product literature should also be consulted.

The first step in an opioid rotation is to calculate the patient’s total daily dose of opioid based on the regularly scheduled dose and the total amount of rescue dose needed in 24 hours. This total is then converted to morphine-dosing equivalents using equianalgesic doses (see Table 34–2). The total daily morphine dose is then used to calculate the daily dose of the new opioid using dosing equivalents from an equianalgesic table. Because cross-tolerance may not be complete between opioids, some references suggest that the calculated equianalgesic dose be reduced by 25% to 50%. If the opioid switch is due to uncontrolled pain, a dosage reduction may not be needed. The calculated equianalgesic dose may need to be reduced more in the medically frail and when converting to methadone.

Methadone appears to be much more potent than once believed, calculated equianalgesic dose may need to be reduced more in the medically frail and when converting to methadone. If the opioid switch is due to uncontrolled pain, a dosage reduction may not be needed. The calculated equianalgesic dose may need to be reduced more in the medically frail and when converting to methadone.

**Patient Encounter, Part 2**

Following surgery she was placed on morphine patient-controlled analgesia (PCA). She has been using 55 mg of morphine/24 hours with adequate pain control; however, she has developed redness and itching on her neck that is believed to be due to the morphine.

**Current Meds:** Morphine PCA; lisinopril 20 mg daily; metformin 500 mg three times daily; lovenox 30 mg subcutaneously daily, until ambulating. She will be discharged to a skilled nursing facility for rehabilitation therapy.

The physician would like to convert her to a combination preparation of hydrocodone and APAP.

**What dosing regimen would you suggest?**

**Recommend a monitoring plan for this patient.**

**How would you assess pain response?**

**The patient is concerned about the redness and itching she developed while on morphine. What other interventions or education may be necessary at this time?**

**Adjuvant Agents for Chronic Pain**

The role of NSAIDs and opioids in chronic nonmalignant pain has been discussed; however, a review of adjuvant agents for...

chronic pain, particularly neuropathic pain, is warranted. Adjuvant analgesics are drugs that have indications other than pain but are useful as monotherapy or in combination with nonopioids and opioids. Common adjuvants include antiepileptic drugs (AEDs), antidepressants, antiarrhythmic drugs, local anesthetics, topical agents (eg, capsaicin), and a variety of other drugs (eg, NMDA antagonists, clonidine, and muscle relaxants).

There is little consensus on the optimal management of neuropathic pain because much of the evidence for treatment effectiveness consists of anecdotal reports or poorly designed trials. Published guidelines have been suggested for the general management of neuropathic pain. \(^{47-50}\) Suggestions for first-line therapy include gabapentin or pregabalin, transdermal lidocaine, or tricyclic antidepressants (TCAs) (Table 34–4). \(^{47-50}\) Newer antidepressants, such as the SSRIs, have fewer side effects but appear to be less effective than the TCAs for neuropathic pain. However, serotonin-norepinephrine reuptake inhibitors (SNRIs), (eg, duloxetine and venlafaxine) have been used successfully for painful DPN. A stepwise approach is suggested for managing the patient with neuropathic pain beginning with the least invasive, effective therapeutic choice and proceeding to the rational use of multiple drug regimens (see Figure 34–2). Choice of agent might also depend on dosing frequency and comorbidities. Data on combination therapy are lacking, and the use of combined treatment is empirical based on the additive therapeutic benefit. Scheduled medication regimens instead of “as-needed” dosing should be used when treating chronic pain, and the effectiveness of therapy should be reassessed regularly. If patients are managed on a multiple drug regimen and changes are indicated, changing only one drug at a time is suggested. Topical agents (eg, capsaicin) might be added to a regimen to reduce the oral medication load, particularly if adverse effects are a problem or if pain is not relieved.

Patient Encounter, Part 3

She was discharged to a skilled nursing facility and is receiving physical therapy and occupational therapy 6 days each week.

Current Meds: Lisinopril 20 mg daily; metformin 500 mg three times daily; lovenox 30 mg subcutaneously daily, until ambulating; hydrocodone/acetaminophen 5/325 mg every 6 hours as needed for pain

Pain Assessment: Patient reports pain of 7 out of 10; worse with movement

Physical therapy notes indicate patient is unable to complete therapy goals due to complaints of pain

Based on this information, what would you recommend as the consultant pharmacist to optimize pain control?

Complementary and Alternative Medicine

Complementary and alternative medicine (CAM) is a term used to encompass a variety of therapies (eg, acupuncture, chiropractic, botanical and nonbotanical dietary supplements, and homeopathy). Painful conditions are among the most common reasons...
individuals seek relief from CAM. A variety of dietary supplements have been suggested for painful conditions such as S-adenosylmethionine (SAM-e), ginger, fish oil, feverfew, γ-linoleic acid, glucosamine, and chondroitin. Of these, glucosamine and chondroitin are the most popular and have the most evidence supporting their efficacy. Glucosamine in doses of 1500 mg/day has been shown to be effective in reducing the pain of osteoarthritis by fostering repair of cartilage, and it is recommended by the Osteoarthritis Research Society International (OARSI).36

OUTCOME EVALUATION
Routine pain assessment is essential for evaluating outcomes of therapy. For example, pain goals for acute pain might include “pain scale less than 3.” Functional goals such as “be able to play a game with grandchildren,” or “be able to knit again” may be appropriate for chronic pain. Assess patients periodically, depending on the method of analgesia and pain condition, for achievement of pain goals. Evaluate the patient for the presence of adverse drug reactions, drug allergies, and drug interactions.

REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Differentiate types of headache syndromes based on clinical features.
2. Recommend nonpharmacologic measures for headache treatment and prevention.
3. Determine when the pharmacologic treatment of headache is indicated.
4. Construct individualized treatment regimens for the acute and chronic management of headache syndromes.
5. Monitor headache treatment to ensure its safety, tolerability, and efficacy.

INTRODUCTION

Headache is a common medical complaint with approximately 47% of the adult population experiencing at least one headache per year. Even when persistent or recurrent, headaches are usually a benign primary condition; secondary headaches are caused by an underlying medical disorder and may be medical emergencies. Primary headache syndromes are the focus of this chapter. Patients may seek headache care from multiple providers. All clinicians should be familiar with the various types of headache, clinical indicators suggesting the need for urgent medical attention or specialist referral, and nonpharmacologic and pharmacologic options for treatment.

The International Headache Society (IHS) classifies primary headaches as migraine, tension-type, or cluster and other trigeminal autonomic cephalalgias.

EPIDEMIOLOGY OF HEADACHE DISORDERS

Migraine Headache

Migraine is a primary headache disorder with an estimated 3-month prevalence rate in the United States of 16.6% to 22.7%, based on data from multiple general health surveillance studies. Prevalence of migraine depends on age, gender, and income. In children and adolescents onset typically begins at age 7.9 years for males and 10.9 years for females. In adults, prevalence is much higher in women (17.1%) than men (6.1%), and occur most often between 30 and 49 years of age. The difference in gender distribution is thought to be due to hormonal differences. In households with an annual income greater than $90,000, migraine prevalence is much lower (13.6% women; 6.2% men) than in households with an annual income less than $22,500 (20.1% women; 8.8% men).

Tension-Type Headache

Tension-Type Headache (TTH) is the most common primary headache disorder and can be further divided into episodic or chronic. TTHs are underrepresented in clinical practice because most patients do not present for care. The term TTH is used to describe all headache syndromes in which sensitization to pericranial nociception, noxious stimuli, is the most significant factor in the pathogenesis of pain. Overall prevalence of TTH is approximately 86%, and incidence is more common in women than men. Episodic TTH is the most common type followed by frequent episodic TTH, and finally chronic TTH. Incidence of TTH increases until approximately age 40, then incidence begins to slowly decline. Environmental factors, as opposed to genetic predisposition, play a central role in the development of TTH. The mean frequency of attacks is 3 days per month in episodic disorders; chronic TTH is defined as 15 or more attacks in a 1-month period.

Cluster Headache and Other Trigeminal Autonomic Cephalalgias

Cluster headache disorders are uncommon and severe primary headache syndromes. In the most recent studies the lifetime prevalence is estimated to be 124 per 100,000. Unlike migraine and TTH, cluster headaches are more frequently found in men. Onset most commonly occurs between 20 and 40 years. A genetic predisposition is apparent, although affected individuals often provide the additional history of tobacco use, caffeine intake, and alcohol abuse. Attacks consist of debilitating, unilateral head pains that occur in series lasting up to months at a time but may abate for extended periods, resulting in months or years between occurrences. In rare instances, cluster headache can be a chronic disorder without remission.

ETIOLOGY AND PATHOPHYSIOLOGY OF HEADACHE DISORDERS

Migraine Headache

The exact mechanism by which migraines produce headache remains obscure, but the belief that only vascular changes are responsible for the pain is no longer accepted. The vascular
hypothesis suggested that intracerebral vasoconstriction led to neural ischemia, which was followed by reflex extracranial vasodilation and pain. Negative neuroimaging evidence for such vascular changes and the effectiveness of medications with no vascular properties make this contention untenable. A neuronal etiology has emerged as the leading mechanism for the development of migraine pain. It is believed that depressed neuronal electrical activity spreads across the brain, producing transitory neural dysfunction. Headache pain is likely due to compensatory overactivity in the trigeminovascular system of the brain. Activation of trigeminal sensory nerves leads to the release of vasoactive neuropeptides (e.g., calcitonin gene-related peptide [CGRP], neurokinin A, substance P) that produce a sterile inflammatory response around vascular structures in the brain, provoking the sensation of pain. Continued sensitization of CNS sensory neurons can potentiate and intensify headache pain as an attack progresses. Bioamine pathways projecting from the brainstem regulate activity within the trigeminovascular system. The pathogenesis of migraine is most likely due to an imbalance in the modulation of nociception and blood vessel tone by serotonergic and noradrenergic neurons.

**Tension-Type Headache**

The pathophysiologic mechanisms producing TTHs are not clearly understood and are likely multifactorial. However, central sensitization to peripheral nociceptive input arising from the pericranial myofascia is the leading hypothesis. The belief that sustained muscle contraction is solely responsible for generating the pain cannot be supported. Muscle tenderness is prominent in this syndrome, but it only reflects a heightened sensitivity to pain. TTH pain is believed to arise by disturbances in the muscles and tissues of the head being misinterpreted due to disordered CNS pain processing.

**Cluster Headache and Other Trigeminal Autonomic Cephalalgias**

Cluster headache is one of a group of disorders referred to as trigeminal autonomic cephalalgias. This autonomic nervous system dysfunction is characterized by sympathetic underactivity coupled with parasympathetic activation. Similar to migraine, the pain of a cluster headache is believed to be the result of vasoactive neuropeptide release and neurogenic inflammation. The exact cause of trigeminal activation in this intermittently manifest syndrome is unclear. One hypothesis is that hypothalamic dysfunction, occasioned by diurnal or seasonal changes in neurohumoral balance, are responsible for headache periodicity. Serotonin affects neuronal activity in the hypothalamus and trigeminal system and may play a role in the pathophysiology of cluster headache. The precipitation of cluster headache by high-altitude exposure also implicates hypoxemia in the pathogenesis of trigeminal autonomic cephalalgias.

**CLINICAL PRESENTATION AND DIAGNOSIS OF HEADACHES**

**Migraine Headache**

Migraine presents as a recurrent headache that is severe enough to interfere with daily functioning. **KEY CONCEPT** Migraine headaches are classified as migraine with aura and migraine without aura. Aura is defined as a transient focal neurologic symptom that can occur prior to or during an attack. These typically present as wavy lines or spots, but can also present as a scotoma. The IHS outlines diagnostic criteria that differentiate migraine with and without aura. Migraines can be triggered by changes in behavior, environment, diet, and hormone levels. Migraines can additionally be triggered by intake of tyramine, aspartame, monosodium glutamate, and nitrates. Migraines occurring 15 or more days per month for a 3-month period or longer, without the overuse of analgesic medications, are classified as chronic migraines. Severe and debilitating migraine pain lasting more than 72 hours is termed status migrainosus.

**Clinical Presentation and Diagnosis of Migraine without Aura**

Patients experiencing “migraine without aura” may display the following headache symptoms and characteristics:

- Two or more of the following present:
  1. Pain interrupts or worsens with physical activity
  2. Unilateral pain
  3. Pulsating pain
  4. Moderate to severe pain intensity

- One or more of the following are present during headache:
  1. Nausea/vomiting
  2. Photophobia and phonophobia

Duration: 4 to 72 hours (treated or not treated)

Criteria for diagnosis: Five or more attacks fulfilling above criteria are necessary

Laboratory assessments that may be helpful in excluding medical comorbidities: Complete blood count (CBC), chemistry panel, thyroid function tests (TFTs), erythrocyte sedimentation rate (ESR)

**Clinical Presentation and Diagnosis of Migraine with Aura**

Patients experiencing “migraine with aura” may display the following headache symptoms and characteristics:

- One or more of the following present with no motor weakness:
  1. Visual
  2. Sensory
  3. Speech and/or language
  4. Motor
  5. Brainstem
  6. Retinal

- Two or more of the following:
  1. At least one aura symptom that spreads gradually over at least 5 minutes
  2. Individual aura symptoms last 5 to 60 minutes
  3. At least one aura symptom is unilateral
  4. The aura is accompanied or followed by a headache within 60 minutes

Criteria for diagnosis: Two or more attacks fulfilling above criteria are necessary
Clinical Presentation and Diagnosis of Tension-Type Headache

Patients experiencing TTH may display the following headache symptoms and characteristics:
- Two or more of the following present and are not aggravated by routine physical activity:
  1. Bilateral pain
  2. Nonpulsating pain
  3. Mild or moderate pain intensity
- Both of the following:
  1. No nausea or vomiting (anorexia possible)
  2. Either photophobia or phonophobia (not both)
- Duration: 30 minutes to 7 days
- Criteria for diagnosis: 10 or more attacks fulfilling above criteria occurring on average less than 1 day per month are necessary

Tension-Type Headache

TTH pain differs from migraine pain in that it is usually reported to be mild to moderate in severity, nonpulsating, and bilateral. The pain is described by sufferers as a band-like tightness or pressure around the head. No transient neurologic deficits are noted, and systemic symptoms are rare. TTH occurring more than 15 days per month for more than 3 months, without evidence medication overuse, would be classified as chronic TTH.

Cluster Headache

Pain associated with cluster headache differs from migraine and TTH in that it is severe, intermittent, and short in duration. Headaches typically occur at night, but attacks may occur multiple times per day. The pain is usually unilateral, but, unlike migraine, it is not described as pulsatile. Aura is not a feature, and pain intensity peaks early after onset, although it may persist for hours. The headache is described as explosive and excruciating. A constellation of features, ascribed to parasympathetic overactivity, can be seen, such as ipsilateral conjunctival injection and lacrimation, rhinorrhea, and sweating. Cluster headache patients tend to become excited and restless during attacks, rather than seeking quiet and solitude as in migraine.

Clinical Presentation and Diagnosis of Cluster Headache

Patients experiencing “cluster headache” may display the following headache symptoms and characteristics:
- At least one or more of the following symptoms:
  1. Lacrimation
  2. Nasal congestion and/or rhinorrhea
  3. Eyelid edema
  4. Forehead or facial sweating/flushing
  5. Sensation of fullness in the ear
  6. Miosis and/or ptosis
  Or a sense of restlessness or agitation
- Duration of pain: 15–180 minutes (untreated)
- Frequency of attacks: One every other day and/or up to 8 per day for more than half the time the disorder is active (may have long periods when headaches are inactive)
- Criteria for diagnosis: Five or more attacks fulfilling the above criteria

Patient Encounter, Part 1

A 34-year-old woman complains of “almost monthly” headaches around the time of menstruation. She states that the pain is so severe that she has to stay home from work and lie down in a darkened room. She describes her pain as sharp, unilateral, and pulsating. She reports that she can tell when it is about to begin because she can see “floaters” then her peripheral vision begins to fade. She reports using OTC pain relievers to help ease the pain, but she has not had any success thus far.

What type of headache is the patient most likely experiencing?

What characteristics of the headache support this diagnosis?

What are possible causes or triggers of headache in this patient?

What additional information is needed to formulate a treatment plan?

TREATMENT OF HEADACHE DISORDERS

Desired Outcomes

The most important goal of acute headache management is pain relief. The short-term treatment goal of migraine is to achieve rapid pain relief to allow the patient to resume normal activities. The long-term goal of therapy is to prevent headache recurrences and to diminish headache severity. Similarly, the goal of TTH care is to lessen headache pain, whereas the long-term goal is to avoid analgesic overuse and dependence.

General Approach to Treatment

First-line pharmacologic agents include nonsteroidal and opiate analgesics, and serotonin-receptor agonists (triptans). Pharmacologic treatment of acute headache should be started early to abort the intensification of pain and to improve response to therapy. The long-term management of headache syndromes focuses on lifestyle modification and other nonpharmacologic therapeutic options; if headaches are severe and frequent, then prophylactic pharmacologic therapy is needed. Several clinical markers, so-called red flags, have been identified that warrant urgent physician referral and further diagnostic evaluation (Table 35–1).

Nonpharmacologic Therapy

The successful management of headache disorders depends on comprehensive patient education. Recording headache frequency, duration, severity, possible triggers, and medication
response in a “headache diary” provides beneficial information for the patient regarding headache precipitants and useful insights for the clinician selecting appropriate management strategies. To prevent future occurrences, exposure to headache triggers (Table 35–2) should be limited. In the acute setting, environmental control can lessen the severity of an attack, so patients may benefit from resting in a dark, quiet area. Behavioral interventions, such as biofeedback, relaxation therapy, and cognitive-behavioral training, are effective and can be recommended for headache prevention. Headache sufferers may also benefit from stress management training. Acupuncture has yielded inconsistent benefits in clinical trials. Although the response is variable, headache patients should be advised to moderate alcohol use and curtail tobacco abuse. All such nonpharmacologic therapies may be useful in augmenting pharmacologic response.

### Pharmacologic Therapy

#### Migraine

Analgesics, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, with or without an opioid, are the initial pharmacologic option for the acute management of migraine headache especially when severity is mild to moderate. If these analgesics prove to be ineffective, and when headaches

are severe, then migraine-specific medications, such as triptans, are administered. Early abortive treatment should be the rule. If the orally administered route is selected for medication administration, then larger doses than otherwise required to produce pain relief may need to be provided, due to the enteric stasis and poor drug absorption accompanying migraine attacks. Intranasal, parenteral, and rectal administration can circumvent this complication. Clinical trial evidence supports many NSAID medications in the acute treatment of migraines with and without aura. Acetaminophen alone or in proprietary combinations with aspirin, opioids, caffeine, or butalbital is also effective.

The triptans are considered specific therapies in that they target the pathophysiology underlying migraine. Triptans inhibit neurotransmission in the trigeminal complex and activate serotonin 1B/1D pathways in the brainstem, which modulate nociception. They also decrease the release of vasoactive neuropeptides leading to vascular reactivity and pain. The triptans are available in intranasal, subcutaneous, and oral dosage forms. The available agents differ in their dosing and pharmacokinetic properties, but all are effective treatments to abort or diminish migraine headache (Table 35–3). Patient responses can be variable; if a patient does not respond to one agent, then another is selected before a patient is prematurely labeled as triptan-unresponsive. The initial severity of headache correlates with symptomatic response; thus administration should be prompt. Relief is usually experienced within 2 to 4 hours. Treatment delay may lead to decreased analgesia through the development of refractory central pain sensitization. Efficacy tends to be dose related, although adverse effects are less so. These medications are well tolerated; the most common side effects are dizziness, a sensation of warmth, chest fullness, and nausea. Rarely, ischemic vascular events may be precipitated by the potential vasoconstrictive nature of these drugs. An initial dose under direct practitioner supervision is indicated for patients at increased cardiovascular risk. Triptans are avoided in patients with migraine associated with neurologic focality, a history of previous stroke, poorly controlled hypertension, or unstable angina. Triptans are relatively contraindicated for routine use in pregnancy. Triptans should not be used with concurrent ergotamine administration.

Ergotamine derivatives produce salutary effects on serotonin receptors similar to triptans. They also impact adrenergic and dopaminergic receptors. Ergotamine tartrate and dihydroergotamine (DHE) are the most commonly used agents. The latter is not available in an oral dosage form. Analgesic onset is within 4 hours, although additional dosing is required if an acceptable

response is not achieved. When dosed parenterally, these drugs are usually provided with an antiemetic due to their potential to worsen the nausea associated with migraine. Metoclopramide and chlorpromazine are the drugs of choice in such instances. Intranasal DHE can be self-administered to abort an attack. The outpatient use of subcutaneous ergotamines is limited by the lack of a prefilled syringe form. The same cautions associated with triptan use are also applicable to ergot use in patients at risk for vascular events.

The choice of initial therapy for acute migraine attacks is a subject of debate among specialists. Some believe that nonspecific analgesics should be used first line, whereas others believe migraine-specific drugs should be the choice for patients with severe pain or a history of significant disability. A stepped-care approach within attacks from less to more specific drugs is usually recommended. Once a history of headache refractory to common analgesics is established, triptans should be used as initial therapy. Selection of initial headache treatment is important in reducing the incidence of medication-overuse headache (MOH). This occurs when patients use ergotamines, triptans, opioids, or other combinations for more than 10 days per month. This can also be considered in patients who are using nonspecific analgesics for more than 15 days per month. In patients who present to the hospital with intractable pain, IV metoclopramide supplemented with DHE may be needed. Oral medications in this setting are not used because nausea and vomiting limit their bioavailability. Migraine patients with frequent and severe attacks are candidates for prophylactic treatment.

### Tension-Type Headache

Most individuals who experience episodic TTHs will not seek medical attention. Instead, they will find relief with the use of widely available OTC analgesics. Acetaminophen products and NSAIDs are commonly utilized. An individual patient may benefit from topical analgesics (eg, ice packs) or physical manipulation (eg, massage) during an acute attack, but the evidence supporting nonpharmacologic therapies is inconsistent. Relaxation techniques can often reduce headache frequency and severity. When pain is unrelied, prescription-strength NSAID use is required, or the combination of acetaminophen with an opioid analgesic may be necessary. The frequent use of these more potent analgesics should be limited, so that the development of dependency is prevented. As described above, MOH can occur with frequent use of analgesics for TTH. For patients experiencing frequent TTH, prophylactic treatment should be considered.

### Cluster Headache

Cluster headache responds to many of the treatment modalities used in acute migraine; however, initial prophylactic therapy is required to limit the frequency of recurrent headaches within a periodic series. A therapy specific to cluster headaches is the administration of high-flow-rate oxygen: 100% at 5 to 10 L/min by nonrebreather face mask for approximately 15 minutes. If the pain is not aborted, retreatment is indicated. No long-term side effects are seen with short-term oxygen use. If oxygen therapy is not wholly effective, then drugs are useful adjunctive therapy. Drug therapy is also used when supplemental oxygen is not readily available. The triptan class is safe and effective. Intranasal or subcutaneous sumatriptan as well as intranasal zolmitriptan has demonstrated efficacy in decreasing cluster headache pain. Oral triptans are also effective, but their delayed onset of action may limit their applicability in acute cluster headache treatment. Cluster headache is rapid in onset and achieves peak intensity quickly, but it can be of short duration. Oral agents may have utility in limiting the recurrence of cluster attacks. Intranasal, intramuscular, or IV ergotamine agents are an alternative to triptan use. Repeated dosing may break a cluster series. For those patients in whom triptans and ergotamine derivatives are contraindicated due to ischemic vascular disease, octreotide may be helpful to relieve pain. Octreotide is a somatostatin analogue that has a short half-life and may be administered subcutaneously. Unlike the other abortive agents, it has no vasoconstrictive effects; the most prominent treatment emergent adverse effect is gastrointestinal (GI) upset. Glucocorticoids, provided IV and later tapered orally, are effective when cluster headache attacks are not satisfactorily controlled.

### Pharmacologic Therapy for Headache Prophylaxis

The choice of pharmacologic agent is individually tailored to patient tolerability and medical comorbidities.

*Level A: Established efficacy.
*Level B: Probably effective.

Data from Refs. 17 and 39.
The β-blockers have long been a mainstay in migraine prevention, and many have been proven to be effective in improving patient symptoms. Cautious dosage titration is advised for those patients who do not have other indications for β-blocker use. Comorbid reactive airway disease is a relative contraindication to β-blocker prophylaxis, and patients with cardiac conduction disturbances should be closely monitored. Calcium channel antagonists are often used when patients cannot tolerate β-blockers. None of the calcium channel blockers carry an FDA indication, and their efficacy is considered to be variable. Angiotensin receptor blockers (ARBs) and angiotensin converting enzyme inhibitors (ACEIs) have been evaluated for migraine prevention, but only two, lisinopril and candesartan, have shown possible efficacy.41

Low-dose amitriptyline or other tricyclic antidepressants (TCAs) are of proven efficacy in migraine prevention.41 Due to sedation, these medications are commonly administered at night. Later generation TCAs (eg, nortriptyline) or heterocyclic compounds (eg, trazodone) have fewer dose-limiting adverse effects than the TCAs, especially anticholinergic effects (eg, dry mouth, constipation, and urinary retention), but efficacy has been variable with these agents. Selective serotonin reuptake inhibitors (SSRIs) and serotonin norepinephrine reuptake inhibitors (SNRIs) have been evaluated for migraine prevention, but thus far, only venlafaxine has demonstrated probable efficacy. Caution is advised when using a serotonergic antidepressant and a triptan concurrently, as the combination may rarely precipitate serotonin syndrome, a serious and potentially life-threatening drug–drug interaction that presents clinically with confusion, GI upset, symptomatic blood pressure (BP) changes, and muscle rigidity.17

The antiepileptics valproic acid and topiramate are approved for migraine prophylaxis. In patients whose migraine headaches are believed to be related to trigeminal neuralgia, carbamazepine is used as prevention for both disorders.31 The precise mechanism of action of these agents is unclear, but enhancement of γ-aminobutyric acid (GABA) neuroinhibition and modulation of the neuroexcitatory amino acid glutamate is likely.44 Divalproex sodium doses are gradually titrated to 1000 mg/day; topiramate is titrated to a maximum of 100 mg twice per day. At these doses, serum drug level monitoring is infrequently needed. These medications are as effective as propranolol at reducing the frequency and severity of migraines and are preferred for prevention in patients intolerant to β-blockers.45 Topiramate is especially useful in patients who have metabolic syndrome, diabetes, and dyslipidemia because it is unlikely to cause weight gain often seen with valproic acid. Patients prescribed topiramate should be advised to stay well hydrated to prevent dysgeusia, disordered taste, and more seriously, hyperthermia.46

Methysergide is an ergotamine derivative that impacts central serotonin balance. Inflammatory fibrosis is a rare but serious, adverse reaction associated with the prolonged use of methysergide. Retroperitoneal fibrosis, pulmonary fibrosis, or fibrosis in cardiac tissue can occur. These conditions may resolve upon drug withdrawal, but cardiac valvular damage can be irreversible. Some experts believe it is the best choice for refractory migraine with frequent attacks, but due to its significant adverse effect profile, it is not marketed in the United States.47

Given that migraines can be triggered by changes in hormonal balance, it is not surprising that some women have migraines around the time of menstruation. Often, these migraines can be prevented by starting NSAIDs prior to the beginning of menstruation. Triptans can be tried in patients unresponsive to NSAIDs. Three triptans have been shown to be effective in preventing menstrual migraines. Frovatriptan, naratriptan, and zolmitriptan can be considered, and should be started 2 to 3 days prior to the beginning of menstruation.41

OnabotulinumtoxinA has received FDA approval for the treatment of chronic migraine, but the evidence supporting its use is conflicting. In 2008, the American Academy of Neurology conducted an evidence review, and concluded that OnabotulinumtoxinA was probably ineffective for the prevention of migraines.46 In the PREEMPT 1 and PREEMPT 2 trials, there was a statistically significant reduction in the number of headache days per month when compared to placebo, but the absolute difference between the two groups was only 1.8 days.49,50

While evidence is limited, some complementary alternative therapies can be considered for migraine prophylaxis. Petasites (butterbur) has been associated with a potential 60% reduction in number of headaches experienced over a 1-month period when compared to placebo. Studies for riboflavin have been mixed, with some older studies supporting its use for migraine prevention, but some newer studies have failed to show efficacy. Finally, MIG-99 (feverfew) has also shown possible efficacy with very limited trial evidence.24

► Tension-Type Headache Prophylaxis

The prevention of chronic TTHs uses the same pharmacologic strategies as for migraine prophylaxis. TCAs are a mainstay of chronic therapy. The efficacy of serotonergic agonists remains in question. Although there is little need for muscle relaxants (eg, methocarbamol) in the treatment of acute TTH, they are often provided as a preventive intervention.7 Combination prophylactic therapies may be needed to weaken patients from daily analgesic abuse. Stress reduction techniques may be particularly effective in this setting.

► Cluster Headache Prophylaxis

The calcium channel blocker verapamil is the mainstay of cluster attack prevention and chronic prophylaxis.7 Within an attack period, it is dosed at 240 to 360 mg/day. Higher doses may be necessary to stave off recurrent cluster periods. Beneficial effects may be appreciated after 1 week of treatment, but 4 to 6 weeks is usually needed. Adverse effects include smooth muscle relaxation with the subsequent exacerbation of gastroesophageal reflux and the development of constipation. Caution should be exercised in patients with myocardial disease because verapamil is an inotropic and chronotropic cardiac suppressant.7 Pharmacokinetic drug–drug interactions must be considered, as verapamil is a potent inhibitor of oxidative metabolism through cytochrome P450 (CYP) enzyme 3A4. Eletriptan is a CYP 3A4 substrate and should not be administered concurrently with verapamil.23,24 Lithium is another effective therapy to reduce headache frequency in a cluster series and to limit recurrences.14 The dose administered should be individualized to achieve a low serum concentration (0.4–0.8 mEq/L [mmol/L]). Dose adjustments in the setting of renal disease or congestive heart failure are required.7 Lithium is contraindicated in patients concurrently prescribed thiazide diuretics and ACEIs or ARBs. Patient persistence with long-term lithium therapy may be hindered by the emergence of tremor, GI distress, and lethargy. Verapamil and lithium doses can be lowered when used in combination with ergotamine. If possible, bedtime dosing is recommended, given the nocturnal predilection of cluster headache attacks.13
Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for the acute and chronic management of this patient’s headache. Your plan should include:

A statement of the drug-related needs and/or problems.

The goals of therapy.

A detailed, patient-specific therapeutic plan.

A monitoring plan to determine whether the goals have been achieved and adverse effects avoided.

SPECIAL POPULATIONS

Migraine Headache in Children and Adolescents

Migraine headaches are common in children, and their prevalence increases in the adolescent years. The diagnosis and evaluation of headaches is especially difficult in children, given their decreased ability to articulate symptoms. Treatment presents another challenge because medications used for headache management in adults have not been fully evaluated for efficacy and safety in children. Consensus panel recommendations identify ibuprofen as effective and acetaminophen as probably effective in the acute treatment of headache in patients older than 6 years. Aspirin use is avoided due to the risk of precipitating Reye syndrome. Antiemetic therapy can be used alone or in combination with analgesics; promethazine is usually prescribed, as it is less prone to cause extrapyramidal reactions than other antiemetics. For adolescents older than 12, triptans are effective and are beneficial for abortive migraine therapy. Medication prophylaxis for migraines in children and adolescents is understudied. The data are conflicting, and no consensus recommendation for the use of preventive drug therapy exists. Nonpharmacologic interventions and trigger identification and avoidance are advised.

Pregnancy

Headaches are more common in women than in men. Fluctuations in estrogen levels are believed to account for this gender discrepancy. Headaches are common in pregnancy. TTHs predominate; migraine attacks may increase in frequency, but more usually frequency decreases during pregnancy. Recommendations for headache care during pregnancy are based on limited evidence and are largely anecdotal. Because headaches are not associated with fetal harm, reflexive pharmacologic therapy should be avoided and drug treatment choices considered carefully. Standard nonpharmacologic therapies are often sufficient. Acetaminophen is safe for the pregnant woman and her fetus. NSAIDs are avoided late in the third trimester to prevent detrimental prostaglandin alterations leading to premature ductus arteriosus closure. Opioids are second-line agents and should not to be used chronically because they can lead to dependence in the mother and to acute withdrawal in the infant after birth. Centrally acting antiemetic agents are safe and may be useful as adjunctive agents. Corticosteroids may be needed for intractable headache relief. Prednisone and methylprednisolone are preferred, as they are metabolized in the placenta and do not expose the fetus. In pregnant women with migraine, vasoconstrictive agents

Patient Care Process

**KEY CONCEPT: Individualized treatment regimens for headache disorders are based on: headache type, pattern of occurrence, response to therapy, medication tolerability, and comorbid medical conditions.**

**Patient Assessment:**
- Assess the patient complaint to yield a detailed description of the headache and to determine if immediate referral for emergency or specialist care is necessary.
- Obtain a complete medical and social history to identify any potential drug–disease interactions or social factors that may influence treatment choices.
- Obtain a family medical history, focusing on headache or mental health disorders in first-degree relatives.
- Complete a review of systems and physical examination to identify causes or complications of headache.
- Determine the type of headache disorder and rule out acute complications.

**Therapy Evaluation:**
- Identify medication allergies, and obtain a thorough history of nonprescription and prescription drug use to identify potential drug–drug interactions that may arise when selecting acute and prophylactic headache treatment.
- If patient is already receiving pharmacotherapy, assess for appropriateness and efficacy.

**Care Plan Development:**
- Recommend appropriate pharmacologic therapy to abort headache based on type, patient characteristics, current medication profile, and comorbid conditions.
- When selecting new agents for acute management or for prophylaxis, ensure that the medication is financially accessible.
- Educate the patient on the administration, maximum dosage, and anticipated adverse effects of the prescribed medication, and advise the patient when to seek emergency medical attention.
- Instruct the patient to keep a headache diary to assess therapeutic response.
- Educate on the potential for medication overuse headache.

**Follow-Up Evaluation:**
- Follow-up should be scheduled within 4 weeks of starting any new medications for headache to assess efficacy.
- As patient becomes more aware of headache symptoms and appropriate agents are on board for prevention and treatment of headache, follow-up can become less frequent (ie, 3–6 months).
such as triptans are relatively contraindicated, even though maternal registry data reveal little teratogenicity. If triptans are considered for acute migraine treatment, sumatriptan, naratriptan, and rizatriptan have the greatest evidence of safe use during pregnancy.\(^5\) Ergot compounds are strictly avoided because they may precipitate uterine contractions and placental ischemia leading to hypoxemia in the fetus. Migraine prophylaxis is considered cautiously because β-blockers and calcium channel antagonists may lead to maternal hypotension and diminished placental blood flow or fetal bradycardia.\(^5\) Antiepileptic drug use in this setting has not been sufficiently studied to allow definitive recommendations.\(^5\)

**Outcome Evaluation**

Monitoring for therapeutic response is an important part of headache management. In acute management, monitor patients for the pain improvement within 2 to 4 hours and for normal functioning within 3 to 4 hours of treatment initiation. If pain control has not been achieved, additional therapy may be needed for a therapeutic effect. With chronic management for headache prevention, monitor overall headache status every several weeks to months for improvement. A slow decrease in headache frequency is anticipated over this time. Encourage patients to track progress in a headache diary to assist in monitoring improvements in frequency and severity of headaches and corresponding disability. Clinicians monitor attack frequency to determine therapeutic response, seeking a 50% or greater reduction over the course of treatment. Monitoring for adverse effects is central to successful treatment. For acute management, monitor for GI effects from analgesics such as NSAIDs or octreotide, vasoconstrictive symptoms from triptans, and nausea and vascular problems from ergot derivatives. Monitor those taking beta blockers for reactive airway disease and cardiac conduction disturbances. Monitor those taking TCAs for sedation and anticholinergic effects such as dry mouth, constipation, and urinary retention. Monitor those taking topiramate for dysgeusia, disordered taste, or hyperthermia. Monitor patients taking calcium channel blockers for gastroesophageal reflux symptoms and constipation, and monitor those taking lithium for tremor, GI distress, and lethargy. To ensure optimal headache management, in acute treatment and prophylactic therapy, monitor regimens both for therapeutic outcomes and adverse events, which may impact quality of life and medication adherence.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify the prevalence of use for commonly used substances (ie, alcohol, opioids, central nervous system [CNS] stimulants, cannabinoids, and nicotine) in the US population.
2. Explain the commonalities of action of abused substances on the reward system in the brain.
3. Identify the typical signs and symptoms of intoxication and withdrawal associated with the use of alcohol, opioids, CNS stimulants, cannabinoids, and nicotine.
4. Determine the appropriate treatment measures to produce a desired outcome after episodes of intoxication and withdrawal.
5. Determine when a patient meets criteria for substance use disorder.
6. Choose specific pharmacotherapeutic options based on patient-specific factors.
7. Recommend a comprehensive medication treatment and monitoring program to help maintain recovery and prevent relapse to substance use.

INTRODUCTION

Substance use disorders are highly prevalent worldwide. In the United States (U.S.), historically, tolerance of substance use and abuse has been cyclical. For example, cocaine was first isolated from coca leaves in 1860. Its use was advocated by many in the medical establishment until around the mid-1890s when it became evident chronic use might be addictive in some individuals and could have deleterious physiologic effects. Its use decreased after restriction of prescribing and dispensing in the early 20th century. In the 1980s, a smokeable formulation of cocaine (ie, crack) became available, and cocaine use again became epidemic. This historically cyclic nature of substance abuse is common to many substances of abuse.

Pharmacotherapy has a role in treatment of some substance-related disorders, including intoxication, withdrawal, and/or long-term relapse prevention. These substances include alcohol, opioids, central nervous system (CNS) stimulants, cannabinoids (CB), and nicotine. This chapter focuses on pharmacotherapy for these common substance-related disorders. Although other substances are misused (eg, prescription sedatives and tranquilizers), those are not the focus of this chapter.

EPIDEMIOLOGY AND ETIOLOGY

The US federal government annually conducts the National Survey on Drug Use and Health (NSDUH) using a representative sample of persons aged 12 years or older to determine the prevalence of licit and illicit drug use. In 2012, more than half (52.1%; 135.5 million) of Americans reported being a current (ie, past month) alcohol drinker. At least once in the 30 days prior to the survey, about one-quarter of Americans (23.0%; 59.7 million) reported binge drinking (ie, 5+ drinks), and 6.5% (17.0 million) reported heavy drinking (ie, binge drinking on 5+ occasions). Approximately one-quarter (26.7%; 69.5 million) were current users of tobacco products, with young adults aged 18 to 25 reporting the highest rates of current tobacco product use (38.1%). Regarding illicit drug use, 9.2% of the US population (23.9 million) reported current illicit drug use, with nonmedical psychotherapeutics being second only to marijuana (Figure 36–1). In 2012, there were 2.9 million illicit drug initiates, with marijuana being the first drug used in a majority of cases (65.6%). Notably, 1.4 million (roughly one-half of the entire drug initiate sample) first-time marijuana users were under the age of 18. Approximately one-quarter nonmedically used a psychotherapeutic as their first illicit drug (ie, 17.0% with pain relievers, 4.1% with tranquilizers, 3.6% with stimulants, and 1.3% with sedatives). The NSDUH findings indicate that substance use is widespread; peaks at 18 to 25 years of age; and consists of a significant number of individuals using prescription medications nonmedically, which is a relatively new and growing public health concern.

Reward Pathway

Virtually all abused substances appear to activate the same brain reward pathway, which is highlighted by dopaminergic neurotransmission arising in the ventral tegmental area (VTA) and projecting to the nucleus accumbens (NA) and prefrontal cortex (PFC).

Figure 36–2 depicts the mesocorticolimbic dopamine pathway. Key components are dopamine (DA) projections from the VTA to the NA and to the PFC. Many studies support that this...
The mesolimbic DA system is involved in natural rewards and drug reinforcement; however, there is also evidence that dopamine-independent reinforcement exists. In any case, abused drugs generally produce pleasant effects considered desirable by the user. The initial hedonic experiences secondary to use of drugs appear to be primarily attributable to activation of primary reward circuits in the brain. These same reward circuits operate under normal circumstances to reinforce activities that promote survival, such as consuming food and water, social affiliation, or sexual activity. However, these systems appear to be disrupted after drug use in susceptible individuals.

Although most individuals experience pleasant effects, not everyone abuses these drugs or becomes dependent on them. Why some persons abuse drugs while most do not relates to complex genetic, environmental, and cultural factors.

**PATHOPHYSIOLOGY**

**Neuronal Adaptation**

**KEY CONCEPT** Although activation of reward pathways explains the pleasurable sensations associated with acute substance use, chronic use (which may result in substance-related disorders) may be related to neuroadaptive effects within the brain.

A recent review by two preeminent researchers in the addiction sciences describes the addiction cycle moving past acute rewarding effects of substances of abuse and into other important processes. They describe three phases of the addiction cycle: (a) binge/intoxication, (b) withdrawal/negative affect, and (c) preoccupation/anticipation. Binge/intoxication refers to the acute rewarding effects of drugs of abuse and the corresponding CNS circuitry. However, chronic use of substances leads to neuroadaptations in the brain and associated symptoms; more specifically, chronic drug abuse appears to cause a generalized decrease in DA neurotransmission. Additionally, with chronic drug use, release of corticotropin-releasing factor (CRF) is increased, indicating an activation of central stress pathways. In phase 3, other neurotransmitter systems (ie, beyond DA) are postulated to be involved. For example, elevated CRF, norepinephrine, and glutamate may exist in the “extended amygdala” during prolonged abstinence. Perhaps these changes lead to a long-term need to use substances to relieve unpleasant symptoms, such as stress. Multiple factors are associated with an increased risk of relapse, including the availability of the abused drug, an increase in psychological stressors, and a triggering of cues such as seeing a white powder or going to a location where drugs were previously attained or used. These factors may trigger residual adaptive changes (eg, elevated glutamatergic activity) that occurred during the period of drug addiction.

**Patient Encounter 1**

A 38-year-old man is being seen in the outpatient clinic for long-term substance use and a recent relapse to oxycodone. The patient has been treated with buprenorphine for close to one year with periods of stability. However, each time there is an attempt at tapering off buprenorphine, the patient experiences intense dysphoria causing him to relapse to oxycodone use. His buprenorphine treatment has been discontinued for approximately three weeks. Recently, he has come to realize that he is reluctant to return home because his girlfriend is still actively using opioids for recreational purposes. However, he states that he is committed to finally “shaking his habit and putting in the work to stay clean.”

**What is the most immediate action to be taken regarding this man’s treatment?**

**After acute detoxification, how can he be helped to maintain abstinence, and is there a medication that offers advantages over other first-line options?**
CHAPTER 36  |  SUBSTANCE-RELATED DISORDERS  547

CLINICAL PRESENTATION AND DIAGNOSIS

KEY CONCEPT Individuals with a pattern of chronic use of commonly abused substances should be assessed to determine if they meet the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5) criteria for substance related disorders. Most notably, in cases of addiction, there is a loss of control over substance use or use has become compulsive. Criteria for substance use disorders from the DSM-5 are listed in Table 36–1. Consistent with the DSM-5, the remainder of this chapter is organized by pharmacologic class and discusses intoxication, withdrawal, and substance use disorders for each class (except tobacco use disorders, which do not have a DSM-5 intoxication criteria set).

Table 36–1

DSM-5 Criteria for Diagnosis of Substance Use Disorders

A problematic pattern of substance use leading to clinically significant impairment or distress; manifested by at least two of the following, occurring within a 12-month period:

1. Substance often taken in larger amounts or over longer period than intended.
2. Persistent desire or unsuccessful efforts to cut down or control substance use.
3. Great deal of time spent in activities necessary to obtain substance, use the substance, or recover from its effects.
4. Craving or a strong desire or urge to use the substance.
5. Recurrent substance use resulting in failure to fulfill major role obligations at work, school, or home.
6. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of substance.
7. Important social, occupational, or recreational activities are given up or reduced because of substance use.
8. Recurrent substance use in situations in which it is physically hazardous.
9. Substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem likely to have been caused or exacerbated by the substance.
10. Tolerance, as defined by either of the following:
   a. Need for markedly increased amounts of substance to achieve intoxication or desired effect.
   b. Markedly diminished effect with continued use of same amount of substance.
11. Withdrawal, as manifested by either of the following:
   a. Characteristic withdrawal syndrome for the substance (refer to Criteria A and B of the DSM-5 criteria set for substance withdrawal).
   b. Substance (or closely related substance) is taken to relieve or avoid withdrawal symptoms.

Specify current severity:
Mild: Presence of two to three symptoms.
Moderate: Presence of four to five symptoms.
Severe: Presence of six or more symptoms.

*Additional specifiers (eg, early vs sustained remission) and substance-specific notes (eg, taking opioid under medical supervision) are included in the DSM-5.

A variety of standardized instruments are available to screen for and assess the various stages of substance use and its consequences, such as withdrawal symptoms and functional impairment (Table 36–2). The Addiction Severity Index (ASI) is the gold-standard instrument that assesses seven problem areas associated with substance use, such as medical status and psychiatric status, in addition to measures of alcohol and drug use.

Intoxication Signs and Symptoms

Intoxication caused by most substances is described in the DSM-5 as clinically significant, problematic behavioral, or psychological changes to the user, which are caused by the physiological effects of the substance. These changes are seen during or shortly after use of the substance. Euphoria or experiencing a pleasurable sensation are effects of most drugs of abuse. Other signs and symptoms are specific to the particular drug or drug class involved. Table 36–3 lists the psychological/behavioral and physiologic effects of intoxication from selected substances.

Withdrawal Signs and Symptoms

Although most abused drugs can cause some degree of physiologic dependence, the severity of withdrawal varies considerably among these drugs. Table 36–4 lists common withdrawal symptoms seen upon abstinence from drug use. Typically, withdrawal symptoms are opposite of acute effects of the drug. For example, although alcohol is a CNS depressant, signs and symptoms of withdrawal signify a hyperalert physiologic response.

TREATMENT OF SUBSTANCE USE DISORDER

OVERALL THEORY OF USE OF PHARMACOLOGIC AGENTS TO TREAT SUBSTANCE-RELATED DISORDERS

Unlike some medical diseases, substance use disorders cannot be cured with medications alone. However, we can sometimes alleviate the effects of drug intoxication, attenuate adverse effects of withdrawal, or somewhat decrease craving and likelihood of relapse to substance abuse. For example, pleasurable and intoxicating effects of opioids appear to be caused by their action as

Patient Encounter 2

A 43-year-old woman with a history of hypertension presents to your clinic for follow-up evaluation of her blood pressure. During the visit, you discover that she admits to drinking a bottle of wine each evening despite her uncontrolled hypertension. She states that her drinking has “crept up” on her over the years and that she finds a bottle of red wine helps to “take the edge off.” The patient states that her strong urges to drink wine at times causes her concern. Notably, she reports experiencing headaches, which she attributes to the combination of red wine and her poor blood pressure management.

What information would suggest this patient might have an alcohol use disorder?
Are there any standardized instruments that you can recommend to screen for an alcohol use disorder?
agonists on μ-receptors of the opioid neurotransmitter system. Competitive μ-opioid antagonists such as naloxone and naltrexone acutely reverse many opioid effects, including symptoms of intoxication. To date, we do not have specific antagonists for most other substances. Similarly, reversal of withdrawal syndromes caused by abused substances is not always possible. One pharmacologic solution for reversing withdrawal symptoms, most commonly used by substance dependent individuals, is to readminister the drug that caused the physiologic dependence. The more commonly used treatment method is to administer a medication that has some cross-dependence with the abused drug but has fewer reinforcing effects and a more predictable pharmacokinetic profile. For example, benzodiazepines are used for the withdrawal of ethanol. Although benzodiazepines can cause physiologic dependence, they are rated as less desirable than ethanol by substance abusers, cause fewer long-term adverse health effects than ethanol, and are easier to manage medically. Regarding long-term medication management, an example is maintaining an opioid-addicted individual on a regimen of medically managed, orally administered opioids (ie, substitution therapy) compared with more dangerous illicit opioid use. Regardless of the specific pharmacotherapy chosen,

medications should always be used as adjuncts to a comprehen-
sive psychosocial approach.

TREATMENT OF INTOXICATION SYNDROMES

KEY CONCEPT The treatment goals for acute intoxication of ethanol, opioids, CNS stimulants, and cannabinoids include (a) management of psychological/psychiatric manifestations of intoxication, such as aggression, hostility, and psychosis and (b) management of medical manifestations of intoxication, such as respiratory depression, hyperthermia, hypertension, cardiac arrhythmias, and stroke. In all cases of substance intoxication that requires medical intervention, referral to and participation in substance abuse treatment is desirable.

Alcohol Intoxication

Desired outcomes are appropriate management of medical problems, prevention of harmful behaviors, and stabilization of mood. Most cases of mild to moderate intoxication with alcohol, including cases with blood alcohol concentrations (BACs) at lower limits of legal intoxication, do not require formal treatment. Providing a safe environment and reassurance until alcohol effects have worn off is sufficient in most cases. Initially, BACs may continue to rise if gastrointestinal (GI) absorption is still occurring. Otherwise, BACs generally decrease at a rate of 15 to 20 mg/dL (0.015%–0.02% or 3.3–4.3 mmol/L) per hour. See Table 36–3 for physiologic effects of alcohol, in nontolerant individuals, at various BACs. It is important to note that tolerant individuals may not show the same level of symptoms at a given BAC as nontolerant individuals.

At more severe levels of intoxication, confusion, stupor, coma, and death may occur. Clinicians must rule out other causes of these serious adverse events, because alcohol-intoxicated individuals commonly combine alcohol with other substances, sustain head or other injuries, and have vitamin deficiencies and electrolyte abnormalities. If consciousness is impaired, then thiamine should be given intravenously (IV) or intramuscularly (IM) at 100 mg/day for at least 3 days. If hypoglycemia is suspected, then thiamine administration should precede administration of glucose-containing fluids to prevent precipitation of acute Wernicke’s syndrome (see Alcohol Withdrawal section). Patients may also develop adverse interactions between alcohol and prescribed medications including disulfiram. See Table 36–5 for drug–drug interactions associated with abused substances.21,14

Behaviorally, patients may insist on driving, become physically aggressive and agitated, or otherwise become a danger to themselves or others. Indeed, most suicidal behaviors among alcohol-dependent individuals occur while they are intoxicated. Antipsychotics may lower the seizure threshold and are best avoided. However, in some instances, agitation may require treatment with an antipsychotic (eg, haloperidol 5–10 mg by mouth every 2–4 hours or olanzapine 10 mg given IM with repeated doses at least 2 hours apart). Sedation with benzodiazepines has been used, but in the presence of alcohol, respiratory depression can be dangerous or even fatal.

There are no medications that can fully reverse the effects of alcohol intoxication. Caffeine and other stimulants are neither indicated nor considered a viable option to make driving safe.

Opioid Intoxication

The word opioid refers to the class of medications and substances that exert their action through the opioid system. Opioids encompass a wide range of substances, including naturally occurring (eg, morphine) and synthetic (eg, oxycodone) substances. Patients who are acutely intoxicated with an opioid usually present with miosis, euphoria, slow breathing, slow heart rate, low blood pressure, and constipation. Seizures may occur with certain agents, such as meperidine (Demerol). It is critically important to monitor patients carefully to avoid cardiac and respiratory depression and death from opioid overdose. One strategy is to reverse intoxication using naloxone (Narcan) 0.4 to 2 mg IV every 2 to 3 minutes up to 10 mg; the IM or subcutaneous (SC) route may be used if IV access is not available. Because naloxone is shorter acting than most abused opioids, it may need to be readministered at periodic intervals; otherwise, patients could lapse into cardiopulmonary arrest after a symptom-free interval of reversed intoxication. In addition, naloxone can induce withdrawal symptoms in opioid-dependent patients, so patients may awaken feeling distressed and agitated. It should be noted that buprenorphine intoxication may be more difficult to reverse.19

It is critically important to secure the airway and ensure breathing in cases of opioid overdose. In some cases, intubation and manual or mechanical ventilation might be required to avoid oxygen desaturation leading to brain hypoxia or anoxia and brain damage or death.

Recently, new opportunities for “take-home” naloxone have emerged in the United States. For example, naloxone hydrochloride injection (Evzio) was Food and Drug Administration (FDA)-approved for this purpose.20 It is too early to determine the public health impact of this approach for treatment of opioid overdoses.

Stimulant (Cocaine and Amphetamines) Intoxication

Desired outcomes of stimulant intoxication treatment are appropriate management of medical and psychiatric problems. Medical problems include hyperthermia, hypertension, cardiac arrhythmias, stroke, and seizures. Some medical problems are related to route of administration, such as nosebleeds with intranasal administration and infections with IV administration. Psychiatric effects include anxiety, irritability, aggression, and psychosis.

Notably, stimulant intoxication is the only stimulant use disorder for which specific pharmacotherapy has demonstrated effectiveness. Recommended medications in acute settings include benzodiazepines, aspirin, nitroglycerin, nitroprusside, and phentolamine.21 The American Heart Association guidelines indicate that acute use of β-blockers is not recommended and may lead to worsening cocaine-related chest pain (caused by coronary vasoconstriction) and hypertension secondary to unopposed alpha activity.

Cocaine is short acting, and a single benzodiazepine sedative-hypnotic may be sufficient treatment for anxiety reactions. Depending on the half-life of the benzodiazepine, one or more sequential doses may be required for longer acting amphetamine intoxication. Antipsychotics are indicated when psychosis is present, and psychosis usually responds quite rapidly in the absence of other co-occurring psychiatric disorders.

Cannabinoid (Marijuana, etc) Intoxication

There are no established treatment recommendations for CB intoxication. Symptomatic treatment (eg, tachycardia, anxiety, paranoia, and psychosis) is the commonly used approach. The exception is potent synthetic cannabinoids, which may require aggressive benzodiazepine treatment for intense symptoms of anxiety or psychosis. These intense psychiatric symptoms have been theorized to result either from the potent full-agonist cannabinoids that are used to prepare them, or possibly due to the

lack of cannabidiol in these synthetic products. Cannabidiol has been associated with antipsychotic effects.

TREATMENT OF WITHDRAWAL SYNDROMES

Key Concept The treatment goals for withdrawal from ethanol, opioids, CNS stimulants, and cannabinoids include (a) a determination if pharmacologic treatment of withdrawal symptoms is necessary, (b) management of other medical manifestations, and (c) referral to the appropriate program for long-term substance abuse treatment. The desired outcomes in the treatment of withdrawal syndromes are to ensure patient safety, comfort, and successful transition from treatment of withdrawal to longer-term maintenance. Referral to specialized treatment for substance use disorders is strongly recommended after treatment of withdrawal syndromes. Achieving a drug-free state by detoxification and then rehabilitation with a focus on total abstinence is the ideal outcome.

Alcohol Withdrawal

Alcohol withdrawal syndromes have two distinct presentations (ie, uncomplicated and complicated), which differ in terms of their pharmacologic treatment and need for hospitalization.

Uncomplicated Alcohol Withdrawal

This is the most commonly observed syndrome, and as the name denotes, is not complicated by seizures, delirium tremens (DTs), or hallucinosis. Symptoms are typically rated using a validated

CYP, cytochrome P450 isoenzyme; LFT, liver function test; MAOI, monoamine oxidase inhibitor.

Caution should always be exercised when combinations of medications with similar pharmacologic properties are used (eg, additive CNS depression associated with coinfection of alcohol and nonmedical use of prescription opioids).

Data from Refs. 17 and 18.
scale such as the Clinical Institute Withdrawal Assessment–Alcohol, Revised (CIWA-Ar) (see Table 36–2). The recommended CIWA-Ar threshold score for treating uncomplicated alcohol withdrawal with medications on an outpatient basis is 8 to 10. For patients who score greater than or equal to 15, inpatient treatment should be considered. Patients who score 20 or higher on the CIWA-Ar should always be treated with medication. The risks of not treating high-scoring patients with medications are seizures and DTs, and those with a prior history of seizures or DTs have increased risk for subsequent episodes. There is some evidence for “kindling” during successive episodes of alcohol withdrawal, such that symptom severity and complications increase with additional withdrawal episodes. Therefore, with a history of seizures or DTs, the lower range of 8 to 10 is recommended, and hospitalization is safer than outpatient detoxification.

Benzodiazepines are the treatment of choice for uncomplicated alcohol withdrawal. Anticonvulsants have been used to treat uncomplicated withdrawal (particularly carbamazepine and sodium valproate); however, they are not as well studied and are less commonly used. The most commonly used benzodiazepines are lorazepam, diazepam, and chlordiazepoxide. They differ in three major ways: (a) their pharmacokinetic properties, (b) the available routes for their administration, and (c) the rapidity of their onset of action due to the rate of GI absorption and rate of crossing the blood–brain barrier. Benzodiazepines are often given in one of two ways: (1) Symptom-triggered approach, or (2) loading dose strategy. Typically, adjunctive “as needed” medications are used as well.

Benzodiazepines can be administered using a symptom-triggered approach when withdrawal signs and symptoms are present. Medication (eg, lorazepam) is administered every hour when the CIWA-Ar is greater than or equal to eight. For example, the shorter-acting agent lorazepam is given at the recommended 1 to 2 mg dose. The CIWA-Ar is repeated hourly after each administration during the first 24 hours until the patient is comfortably sedated. Due to a short half-life, dosing of lorazepam on subsequent days may be needed, and risk of seizures may possibly (although not definitively proven) be higher.

Longer-acting agents (eg, diazepam, chlordiazepoxide) are often used via the loading dose strategy in which larger doses are given initially followed by a taper over 3–5 days. The long half-lives of these drugs and their active metabolites usually provide a natural taper without further drug administration. This approach may be accompanied by as needed short-acting benzodiazepine doses for breakthrough alcohol withdrawal symptoms. The loading dose strategy is especially useful in the hospital, where patients can be medically monitored throughout the day. Diazepam may be “preferred” to chlordiazepoxide, given its less variable pharmacokinetic profile (eg, fewer active metabolites, narrower range for time to maximum concentration) and a faster onset of action (ie, quickly enters the CNS due to high lipophilicity).

**Special Dosing Considerations** In contrast to chlordiazepoxide and diazepam, lorazepam is not metabolized into active compounds in the liver. It is excreted by the kidneys after glucuronidation. This is important because many alcohol-dependent patients have compromised liver function. Therefore, when treatment is initiated before results of liver function tests (LFTs) are known, lorazepam may be preferred. Patients with liver disease may still be treated with diazepam or chlordiazepoxide at lower doses.

Diazepam is more lipophilic than lorazepam or chlordiazepoxide, resulting in quicker GI absorption and passage across the blood–brain barrier, making it valuable in an inpatient setting, especially to prevent seizures. However, a faster onset of action may be associated with feeling high (ie, “euphoria”) and is a treatment disadvantage.

**American Psychiatric Association (APA) Guidelines** recommend thiamine be given routinely to patients being treated for moderate to severe alcohol use disorders to treat or prevent adverse neurologic symptoms. However, according to a recent Cochrane Review, there are inadequate data from randomized, controlled trials regarding the most efficacious thiamine dose, frequency, and route of administration to prevent or treat Wernicke’s syndrome associated with alcohol use disorders. APA Guidelines recommend thiamine 50 to 100 mg per day given IV or IM, although some guidelines recommend higher doses (eg, thiamine 300 mg/day for low risk patients). It is particularly important that administration of thiamine (essential for proper energy utilization by the CNS) precedes administration of glucose-containing IV fluids, which can help prevent an acute exacerbation of Wernicke’s syndrome.

**Complicated Alcohol Withdrawal**

**Alcohol Withdrawal Seizures** Alcohol withdrawal seizures, a medical emergency, should be treated in an inpatient setting. Withdrawal seizures are usually few in number and generalized. Although binge drinking and alcohol withdrawal can lead to status epilepticus, the occurrence of focal seizures or status epilepticus may also suggest another etiology. Management consists of keeping the airway open and preventing self-injury during convulsions. Benzodiazepines are the treatment of choice. IV diazepam 5 to 10 mg is preferred to terminate a seizure in progress if IV access is available. Dose may be repeated in 5 minutes if seizures persist. Alternatively, lorazepam 4 mg may be given IM followed by injection of an IV line when convulsive movements have subsided. In the event of a recurrent seizure, lorazepam 2 mg IV may be administered if the patient received IM lorazepam. IM use of diazepam or chlordiazepoxide should be avoided because of erratic absorption that complicates the timing of subsequent doses and can result in delayed oversedation. IV benzodiazepines may depress respiration, so they should be administered only when and where advanced cardiopulmonary support is available. When the patient can take medication orally, then treatment may continue using the symptom-triggered or loading dose procedure. Electrolyte imbalances can contribute to seizures and should be corrected if they exist. For example, it may be advisable to administer magnesium in addition to benzodiazepine treatment. Phenytoin should be avoided for preventing or treating alcohol-related seizures as no data demonstrate efficacy.

**Alcohol Withdrawal Delirium (Delirium Tremens)** Delirium tremens is a medical emergency necessitating hospitalization to prevent death. DTs are characterized by hallucinations, delirium, severe agitation, fever, elevation of blood pressure and heart rate, and possible cardiac arrhythmias. Parenterally administered benzodiazepines are the treatment of choice. The antipsychotic haloperidol is given for severe agitation unresponsive to benzodiazepine therapy. Evidence does not support use of an antipsychotic as single agent. Furthermore, newer generation antipsychotic agents have not been studied for treatment of DTs. Thiamine should be given according to the same guidelines described above.

**Opioid Withdrawal**

It is rare to die from withdrawal from opioids alone; however, underlying medical complications (eg, hypertension) and recent
myocardial infarction increase risk of complications and death. Therefore, it is important to manage and stabilize any medical issues and then determine if hospitalization is appropriate. Patients with underlying medical problems should be evaluated for possible triage to an inpatient detoxification program to be followed up with either inpatient or outpatient substance abuse treatment. Rapid referral for substance abuse treatment can introduce patients to the concept of recovery while they still vividly remember negative consequences from using substances. Withdrawal from opioids is commonly described by patients as resembling “a bad case of the flu.” Symptoms include nausea; vomiting; diarrhea; anxiety; headaches; mydriasis; rhinorrhea; lacrimation; muscle, bone, and joint pain; piloerection; yawning; fever; increased heart rate; and hypertension.

Use of clinical withdrawal scales (see Table 36–2), such as the Clinical Opiate Withdrawal Scale (COWS), provide high inter-rater reliability and clinical utility given objective measurement of withdrawal severity. The full items contained in the COWS instrument (along with many other substance use disorder [SUD] instruments) can be obtained free-of-charge from the Substance Abuse and Mental Health Services Administration (SAMHSA). The baseline score assists in deciding whether to treat pharmacologically or to observe. As withdrawal scores become larger (eg, COWS scores five or greater), opioid substitution or a “symptoms-based approach” may be indicated. In severe withdrawal, either buprenorphine (ie, partial μ-opioid agonist) or methadone (ie, full μ-opioid agonist) are recommended for detoxification. Methadone is the gold-standard μ-opioid agonist for treating opioid use disorders, but under current US law, methadone detoxification requires referral to a federally approved methadone detoxification program. The two pharmacologic options for treatment of opioid withdrawal in regular clinical settings are opioid substitution with buprenorphine and symptomatic treatment (discussed in the following paragraphs).

### Opioid Substitution

Treatment with a μ-opioid agonist is accomplished with either buprenorphine or methadone. Methadone can be used for opioid detoxification and long-term relapse prevention, particularly among heavy opioid users. However, given extensive medical use restrictions (eg, used only in federally approved opioid treatment programs; OTP) and wide availability of methadone detoxification regimens, this chapter focuses on buprenorphine.

Buprenorphine is a partial agonist at μ-opioid receptors that is available in multiple formulations in the United States with varying pharmacokinetic profiles. For example, buprenorphine in combination with naloxone is available via sublingual tablet, sublingual film, and buccal film. Certain formulations (eg, sublingual film) may have greater buprenorphine bioavailability, and hence lower dosage requirements, compared to sublingual tablets. Buprenorphine plus naloxone is the recommended formulation (over buprenorphine alone) unless the patient is pregnant or hypersensitive to naloxone, in which case buprenorphine alone is appropriate. Opioid antagonists, such as naloxone, have been associated with severe negative outcomes among pregnant women (eg, spontaneous abortion) and should be avoided in this population. Naloxone was added to the Suboxone formulation to secure FDA approval in the United States. Naloxone is poorly absorbed via sublingual or buccal routes, but blocks opioid receptors if injected, thus minimizing diversion to the street for IV use.

To initiate buprenorphine induction, a patient has to be in moderate or severe withdrawal, and the last opioid used should be at least 12 to 24 hours earlier, depending on the half-life of the opioid used (longer half-life, longer a clinician should wait before initiating buprenorphine induction). Otherwise, buprenorphine likely will induce withdrawal because it has high affinity for μ-receptors, and it will displace other full μ-opioid agonists. Buprenorphine can be initiated following a protocol such as the example in Table 36–6 to titrate the dosing. When a final dose is established, there are generally two treatment approaches, depending on many factors such as patient preference. A maintenance dose can be prescribed or the dose can be tapered down gradually to zero within 1 to 2 weeks (a 25% reduction per day is a general rule of thumb).

### Symptoms-Based Treatment

Symptomatic treatment focuses on minimizing withdrawal symptoms to help patients be comfortable. Symptom-specific medications, as shown in Table 36–7, are often used as adjunct

**A “Symptoms-Based” Treatment Approach for Opioid Withdrawal**

Following medications are used for symptoms that cause distress and includes use of any single or combination of two or more of the following agents, depending on symptoms reported:

1. Insomnia: Diphenhydramine 50–100 mg, trazodone 75–200 mg, or hydroxyzine 25–50 mg at bedtime
2. Headache, muscle aches, and pain: Acetaminophen 500 mg–1 g every 6 hours, ibuprofen 600 mg by mouth every 8 hours, or naproxen 500 mg by mouth every 12 hours
3. Noradrenergic hyperactivity: Clonidine (Catapres) 0.1–0.2 mg every 6–8 hours; maximum dosage not to exceed 1.2 mg in 24 hours
4. Abdominal cramps: Dicyclomine 10–20 mg every 6 hours
5. Constipation: Milk of magnesia at 30 mL daily
6. Diarrhea: Bismuth subcarbonate 30 mL can be given every 2 to 3 hours

Data from Refs. 9 and 12.
medication with opioid substitution. Clonidine is one of the primary nonopioid medications used during withdrawal to decrease the excessive noradrenergic symptoms (eg, sweating) of opioid withdrawal. However, use of clonidine requires close monitoring of blood pressure; it should be held if systolic blood pressure is below 90 mm Hg or diastolic blood pressure is below 60 mm Hg. Compared with opioid substitution, clonidine does not help other withdrawal symptoms, such as craving.

- **General Patient Guidelines for Outpatient Opioid Detoxification**

Patient safety is the highest priority. The first step is to educate patients about the course of withdrawal. Symptoms peak at around 5 to 7 days and may last up to 2 weeks, depending on half-life of the opioid being used before detoxification. Patients should be advised regarding the side effects of medications used to detoxify. There is an overdose potential if clonidine is mixed with opioids, other CNS sedatives, or antihypertensives. Risk of these adverse events needs to be balanced with potential benefits. Side effects of buprenorphine include constipation, sedation, and headaches. Potential for serious overdose exists when buprenorphine is mixed with benzodiazepines or other sedative–hypnotics.

Risk of developing physiologic tolerance to buprenorphine is high if used for prolonged periods. In this case, buprenorphine should be slowly tapered to discontinuation. Withdrawal from buprenorphine is generally easier and less severe than withdrawal from a pure agonist, such as methadone. However, there is concern regarding a subset of patients who have difficulty stopping buprenorphine treatment. This has prompted federal research into the issue (see www.clinicaltrials.gov regarding ongoing studies). The duration of buprenorphine treatment is specific to each individual’s needs and resources, and difficulty in tapering the medication to discontinuation complicates this decision further.

Patients often think all they need is detoxification, but this is not accurate. Positive outcomes are tied to successful rehabilitation and acquiring recovery skills after detoxification. This goal can be accomplished by either achieving detoxification on-site during rehabilitation or by quick and seamless transition from detoxification to a rehabilitation program. The more time that elapses between the two modalities, the greater the likelihood of treatment failure and drug relapse.

**Stimulant (Cocaine, Amphetamines) Withdrawal**

Cocaine and amphetamine withdrawal are grouped together because their symptom profiles as described in DSM-5 are similar, and the physiologic basis of their withdrawal syndromes involves the DA neurotransmitter system. Stimulants of this group also include methylenidate, but not nicotine and caffeine, which have different neurophysiologic mechanisms of action. Major adverse complications of stimulant withdrawal are profound depression with suicidal thoughts, and the primary goal of treatment is to prevent suicide. Therefore, unless suicidality warrants hospitalization, stimulant withdrawal can be treated in outpatient settings with psychological support and reassurance with an emphasis on patient safety. A number of medications have been studied to alleviate symptoms of stimulant withdrawal and the intense craving that may accompany it, but inconsistent results preclude any recommendations for their routine use. Patients with stimulant use disorders should be referred for substance abuse treatment because of high risk for continued use either during or immediately following stimulant withdrawal.

**Cannabinoid (Marijuana, Hashish) Withdrawal**

Symptoms of cannabinoid withdrawal are primarily behavioral. For example, significant anxiety may accompany cannabinoid withdrawal, which can lead many individuals to resume substance use. This is particularly problematic following heavy and prolonged cannabinoid use. Management of withdrawal focuses on these behavioral symptoms, as there are no FDA approved medications specifically targeted at cannabinoid withdrawal.

**GENERAL APPROACH TO THE TREATMENT OF SUBSTANCE USE DISORDERS**

- **Key Concept**: A multimodal and comprehensive approach is preferred when treating individuals with substance use disorders given the heterogeneous nature of addiction. Pharmacologic treatment is always adjunctive to psychosocial therapy. Steps to be taken in the management of addiction are similar for all substances, and are highlighted in the Patient Care Process.

Comorbid psychiatric conditions such as anxiety, depression, insomnia, pain, and continued smoking should be addressed. All these conditions increase risk of relapse to drug use. Although complete abstinence may be desirable in many patients, decreasing substance use and negative consequences may be sufficient in certain cases (ie, “harm reduction” concept).”

**Nonpharmacologic Therapy**

Although pharmacologic agents may help prevent relapse, psychotherapy should be the core therapeutic intervention. Psychotherapy typically addresses one or more of the following tasks:

- Motivation enhancement to stop or reduce drug use
- Coping skills education
- Providing alternative reinforcement
- Managing painful affect (eg, dysphoria)
- Enhancing social support and interpersonal functioning

A thorough review of these psychosocial approaches is beyond the scope of this chapter and are available elsewhere. However, a few of the commonly used techniques are cognitive-behavioral therapy (CBT), motivational-enhancement therapy (MET), and other behavioral therapies (eg, community reinforcement).

**Pharmacologic Therapy**

- **Maintenance Treatment**

Certain pharmacologic agents have been shown to be helpful for long-term maintenance in patients with substance use disorders. Typically, these medications exert their effects by one of the following theorized mechanisms: (a) drug substitution therapy with an agonist, (b) blocking drug effects with an antagonist, and (c) miscellaneous relapse prevention medications with indirect mechanisms of action. Medications from each of these categories are discussed in greater detail in the following paragraphs for alcohol, opioid, cannabinoid, stimulant, and tobacco use disorders.

- ** Alcohol Use Disorder**

The three FDA-approved medications to treat alcohol use disorders are naltrexone (oral and depot), acamprosate, and disulfiram. Naltrexone and acamprosate are generally considered first-line agents as evidenced by their “grade A” efficacy rating in the seminal paper by Garbutt et al. However, in motivated patients, disulfiram is another reasonable option.
**Naltrexone**

Naltrexone is a competitive opioid antagonist that decreases alcohol intake in both animals and humans. Evidence suggests that it both decreases craving for alcohol and alcohol-induced euphoria (ie, reduces positive reinforcement of drinking). Numerous controlled trials and meta-analyses have demonstrated that naltrexone is more efficacious than placebo for a variety of drinking measures. One meta-analysis that included more than 20 controlled trials demonstrated naltrexone significantly decreased relapse risk compared with placebo. Reported predictors of naltrexone efficacy include family history of alcoholism, genetic differences in opioid alleles, drinking problems at early age, and high levels of craving. In a landmark study assessing efficacy of behavioral treatment, medication management, and their combinations for treatment of alcohol dependence, naltrexone was associated with a higher percent days abstinent. An oversimplified interpretation of this complex study suggests that naltrexone was effective (eg, percent days abstinent), but that acamprosate was not associated with any treatment advantage.

Naltrexone is available in both oral and sustained-release injections. Usual oral dose of naltrexone is 50 mg/day, with a range from 25 to 100 mg. The 25-mg dose is commonly given initially as a test dose and then increased to 50 mg/day as tolerated. Adherence to naltrexone strongly affects drinking outcomes; therefore, a sustained-release IM injection of naltrexone has been marketed. A 380-mg monthly injection of naltrexone (Vivitrol) resulted in significantly greater reductions in heavy drinking days compared with placebo injection.

- **Most common naltrexone side effects are nausea, vomiting, headache, insomnia, and nervousness.** Injectable naltrexone is associated with injection site pain or reactions. Because naltrexone can precipitate withdrawal in patients dependent on opioids, the first dose should be withheld 7 to 10 days after last opioid use and given only when urine drug screen for opioids is negative. Naltrexone can be hepatotoxic, albeit typically not at oral doses less than 250 mg/day or at recommended injectable dose of 380 mg/mo. Baseline and periodic LFTs are recommended.

**Drug Interactions**

Naltrexone can block effects of opioid receptor agonists, rendering them therapeutically ineffective (see Table 36–5). Given that opioid agonists are a mainstay of pain management, alternative pain treatment (eg, conscious sedation) may be required in patients receiving naltrexone maintenance.

**Special Dosing Considerations**

It is important for patients taking naltrexone to carry a pocket warning card or wear a warning bracelet because, in the event that emergency treatment is needed, they will be insensitive to opioid analgesia unless potentially toxic doses are administered. Patients need to be warned of the potential for opioid overdose under two conditions. First, dosing with opioids to reverse opioid insensitivity (ie, naltrexone’s competitive blockade of opioid receptors) requires high doses of opioids that can cause respiratory depression and death. Second, chronic opioid antagonist therapy may cause patients to become hypersensitive to opioids after stopping naltrexone, thereby increasing risk of respiratory depression and death when opioids are used.

**Acamprosate**

Acamprosate appears to be a glutamatergic antagonist and may have GABA-ergic effects. Alcohol use acutely inhibits glutamatergic function. During acute and postacute alcohol withdrawal, increased activity of the glutamate system is caused by upregulation of receptors combined with absence of alcohol-related inhibition. Thus, acamprosate may correct glutamate/GABA imbalances that occur following chronic alcohol use (eg, reduce negative reinforcement associated with craving and withdrawal).

Generally, trials assessing efficacy of acamprosate have shown mixed results. This may be partly attributable to differences in research methodologies, such as varying levels of abstinence required in trials before acamprosate initiation. Notably, in the landmark Combining Medications and Behavioral Interventions for Alcoholism (COMBINE) study mentioned earlier, acamprosate appeared to offer no treatment advantage, but a meta-analysis of randomized control trials suggests it is more efficacious than placebo. Another recent meta-analysis suggests that acamprosate may be more effective at maintaining abstinence, but naltrexone may more effectively prevent full relapse to heavy drinking in nonabstinent individuals. Despite the variable methodologies and results, there appear to be sufficient evidence that acamprosate is more effective than placebo, although differences may be modest.

The dose of acamprosate is 666 mg orally three times daily. It is not metabolized by the liver and is excreted unchanged by the kidneys. Consequently, it is contraindicated in patients with severe renal impairment (creatinine clearance less than or equal to 30 mL/min [0.50 mL/s]), and dose reduction is necessary when creatinine clearance is between 30 and 50 mL/min (0.50 and 0.83 mL/s). Most common acamprosate side effects are GI, including nausea and diarrhea. CNS adverse effects include insomnia, anxiety, and depressive symptoms.

**Disulfiram**

Disulfiram irreversibly blocks the enzyme aldehyde dehydrogenase (ALDH), a step in the metabolism of alcohol. This results in increased blood levels of the toxic metabolite acetaldehyde. As acetaldehyde levels increase, patients experience the disulfiram–ethanol reaction (decreased blood pressure, increased heart rate, chest pain, palpitations, dizziness, flushing, sweating, weakness, nausea and vomiting, headache, shortness of breath, blurred vision, and syncope). Symptom severity increases with amount of alcohol consumed, and emergency treatment may be warranted. Psychologically, disulfiram works through aversion, and drinking is avoided to prevent the aversive disulfiram–ethanol reaction. Efficacy of disulfiram is directly dependent on medication adherence, and more recent reports advocate that disulfiram can be highly effective when procedures for enhancing adherence are used.

The usual starting dose of disulfiram is 250 mg/day orally (can be started at 500 mg/day for first 1 to 2 weeks), and the range is 125 to 500 mg/day. Compared with 250 mg/day, the larger dose is recommended if a patient does not experience a disulfiram–ethanol reaction after alcohol consumption, and the smaller dose is given when intolerable side effects are experienced at higher doses. Dosing begins only after the BAC is zero (usually 12–24 hours after the last drink) and after the patient understands the consequences of the disulfiram–ethanol reaction.

- **Disulfiram is contraindicated in patients with cardiovascular or cerebrovascular disease or in combination with antihypertensive medications because the cardiovascular effects of the disulfiram–alcohol reaction could be fatal in such patients.
- Most common disulfiram side effects are rash, drowsiness, a metallic or garlic-like taste, and headache. If drowsiness occurs, dose may be lowered or given at night. Other less common, but concerning, adverse effects include neuropathies and hepatotoxicity. Given the serious nature of these adverse effects, baseline and periodic monitoring is recommended. If serum levels of alanine
aminotransferase (ALT) or aspartate aminotransferase (AST) are greater than three times the upper limit of normal values, then disulfiram should be withheld and testing repeated every 1 to 2 weeks until normal. When LFTs return to normal range, they may be repeated every 1 to 6 months. It is advisable to follow LFTs and clinical symptoms until resolution has been confirmed. Although elevated LFTs may signal disulfiram-induced hepatotoxicity, it is also likely the patient was nonadherent to treatment and resumed drinking, ultimately leading to hepatotoxicity. Another uncommon side effect of disulfiram is psychosis, which has been reported in doses exceeding 500 mg/day, especially in predisposed patients. This may be related to disulfiram’s ability to inhibit dopamine β-hydroxylase, resulting in increased dopamine activity. Nevertheless, alcohol-dependent patients with schizophrenia and other cooccurring mental disorders have received disulfiram at usual therapeutic doses without difficulties.

**Drug Interactions** The disulfiram–ethanol interaction serves as disulfiram’s mechanism of action. Depending on dose of disulfiram, sensitivity to disulfiram, amount of alcohol consumed, and metabolism, patients may be at risk for an adverse interaction with alcohol for 2 to 14 days after stopping disulfiram (5 days on average) and should be warned accordingly. See Table 36–5 for relevant interactions that occur with disulfiram (particularly with metronidazole).

**Medication Selection** See Table 36–8 for patient-specific factors that can guide medication selection for alcohol use disorders. Universally accepted treatment algorithms for the treatment of alcohol use disorders are lacking.

### Opioid Use Disorders

After conclusion of withdrawal, patients may not feel their usual selves for some time and could relapse to using opioids, just to “feel normal.” Long-term use of opioids results in brain changes,

---

**Patient Encounter 3**

A 19-year-old woman was transferred to the cardiology unit from the emergency department (ED) after she called 911 claiming that she had chest pain and that her heart was racing. This in turn caused her significant anxiety. Upon arrival in the ED, it was noted that her heart rate was 130 beats/min in a resting position. She was in otherwise good physical condition with no previous cardiac history, although her eyes appeared extremely red and hazy. After a comprehensive urine toxicology analysis was positive for cannabinoids, she admitted that she had used “K2” at a party. She said she almost never uses illegal drugs. However, she was told “K2” could “help her anxiety” (diagnosed with generalized anxiety disorder at age 15 years), which has worsened since starting college. The treatment plan is to address the patient’s substance use and anxiety disorder after the acute cardiac issues are resolved.

What physical signs and symptoms does she manifest that are consistent with cannabinoid intoxication?

What is the most appropriate pharmacotherapy for this patient’s acute substance use condition?
and the brain might not readily return to its prior homeostasis. The goal of treatment is to encourage stability, both in the body and in the patient’s life. If an individual is not successful in quitting opioids (eg, because of withdrawal symptoms or postacute craving), then maintenance treatment should be considered.

**Opioid Agonists** The time-honored opioid agonist treatment for opioid use disorders is methadone maintenance. However, methadone maintenance can be provided only in federally approved OTPs. The other first-line agent, which will be the focus of this chapter, is buprenorphine maintenance.

The more widely available office-based opioid treatment (OBOT) exclusively uses buprenorphine, a partial μ-agonist (typically in same medication formulation with naloxone). Under provisions of the Drug Addiction Treatment Act of 2000, physicians may prescribe buprenorphine in their office if they meet predetermined requirements (eg, training) and become qualified providers. When these criteria are met, they obtain an “X” on their Drug Enforcement Administration (DEA) number.

The effective maintenance dose of buprenorphine (with or without naloxone) is usually between 8 and 16 mg/day, with maximum reported efficacy at 64 mg/day. Patients receiving buprenorphine maintenance should sign a treatment contract requiring full adherence, financial responsibility for treatment, adherence to office policies, respectful behavior to staff, and agreement to provide random urine samples for drug screens. Patients should bring their prescribed medication for pill counts at every visit. In the event of OBOT failure, the alternative to buprenorphine maintenance is referral to an OTP for methadone administration.

In 2010, the injectable formulation of naltrexone was approved for prevention of opioid relapse following successful opioid detoxification. However, its place in the long-term treatment of opioid use disorders remains to be established. Please refer to alcohol use disorder section for additional naltrexone drug information. Chronic naltrexone use may complicate the risk of overdose with full opioid agonists as described above.

Although there are no treatment algorithms to guide medication selection, there are protocols for some medications that assist with dosing and titration. For example, the extensive buprenorphine treatment protocol available from SAMHSA provides guidelines on how to dose buprenorphine from induction to maintenance treatment. Of note, findings from a recent Cochrane meta-analysis indicate that methadone may offer an advantage over buprenorphine for select treatment outcomes (eg, retention in treatment). Therefore, there may be circumstances under which referral to methadone maintenance remains the best option.

**Cannabinoid Use Disorders**

There are no proven pharmacotherapies for treatment of cannabinoid use disorders. Pharmacotherapy trials have emerged in the literature, but it is too soon to evaluate the role of medications for the treatment of cannabinoid use disorders.

**Stimulant Use Disorders**

There are no proven pharmacotherapies for treatment of stimulant use disorders. However, the APA Practice Guidelines mention three medications as possible treatment options for CNS stimulant use disorders when combined with psychosocial approaches (ie, after psychosocial approaches alone have failed). These medications include topiramate, disulfiram, and modafinil. For example, disulfiram shows some promise in randomized, controlled trials possibly due to its inhibition of dopamine β-hydroxylase enzyme that converts DA to norepinephrine (NE) in the brain. The resulting increase in DA levels may counter DA deficiency states that are believed to underlie cocaine withdrawal and craving.

**Tobacco Cessation**

**Nonpharmacologic** Behavioral treatment delivered by a variety of clinicians (eg, physician, psychologist, nurse, pharmacist, and dentist) increases abstinence rates. The five As should be applied by all clinicians:

- Ask if they smoke.
- Advise to quit.
- Assess motivation for change.
- Assist if willing to change.
- Arrange for follow-up.

Smoking cessation counseling should be provided to all smokers, and those interested should be assisted to achieve cessation. It is now a standard of practice for clinicians to screen for smoking and provide all smokers with brief advice and assistance with appropriate medications to quit or provide referral to specialized services when needed.

**Pharmacologic** According to the seminal tobacco use clinical practice guideline, there are seven first-line medications available to treat nicotine use disorders (Table 36–9). Symptomatic detoxification and maintenance for tobacco use disorders is achieved with any single or combination of the currently available nicotine replacement therapies (NRTs). Similar to opioid agonists, these NRTs act as substitution therapy with a safer alternative. NRT is generally considered safe with one notable exception: Given the pregnancy category D assigned to NRT, the decision to use NRT for pregnant women must be made on a case-by-case basis. According to clinical practice guidelines, pregnant smokers should be encouraged to quit smoking without use of medication. Given the various NRT products that are efficacious at treating tobacco use disorders, choice of specific NRT depends on other factors, such as patient preference.

First-line non-nicotine medications proven beneficial for treating tobacco use disorders are bupropion and varenicline. The sustained-release form of the antidepressant bupropion (Zyban) was approved by the FDA for treatment of tobacco use disorders. Bupropion blocks reuptake of DA and NE, and it appears that one of its metabolites is a nicotinic antagonist. These mechanisms may help explain how bupropion acts to reduce nicotine reinforcement, withdrawal, and craving.

Varenicline (Chantix) is a αβ nicotinic acetylcholine (nACh) partial agonist. Varenicline decreases withdrawal and craving and prevents reinforcing effects of nicotine if the patient relapses. It is at least as effective as bupropion in clinical trials. Both bupropion and varenicline have been associated with severe psychiatric disturbances when used for smoking cessation.

As shown in Table 36–10, various NRTs, bupropion, and varenicline increase abstinence rates at 6 months compared to placebo. Furthermore, combining the nicotine patch with ad libitum nicotine gum provides the highest likelihood of abstinence at 6 months. The single agent (ie, monotherapy) with the highest odds of maintaining abstinence is varenicline (2 mg/day dose).

OUTCOME EVALUATION

A major component of successful treatment of substance use disorders is to monitor use of medications and identify a mechanism for long-term support of sobriety that might be appropriate for a specific individual such as AA, or recovery programs for professionals such as doctors, nurses, and pharmacists.

To determine immediate treatment outcomes for patients with intoxication and withdrawal syndromes, evaluate parameters such as blood pressure, heart rate, respirations, and body temperature, as well as mental state. Choose from a number of validated and standardized rating scales to monitor the responsiveness of withdrawal syndromes to medical treatment. To determine the overall effectiveness of your health system for the treatment of substance related disorders, monitor outcomes using sentinel events such as the rates of cardiopulmonary arrest, seizures, discharges against medical advice, patient violence, and use of physical restraints. The ultimate goal should be to enable the transition of patients to formal substance use treatment when indicated.

Important outcome indicators to evaluate postintoxication and/or postwithdrawal treatment can be divided into three major groups: decreased consumption of substances, decreased problems associated with substance use, and improved psychosocial functioning. When complete abstinence has not been achieved, quantify the consumption of substances using quantity-frequency measures, rates of abstinence, and time to first relapse as determined by interviews and self-report and by biological markers such as urine and blood tests. The Addiction Severity Index (see Table 36–2) can be used to assess alcohol and drug-related problems in various domains, and provides a more comprehensive picture of the substance user’s life.

Clinicians must be familiar with “essential” resources, many of which are in the public domain. Table 36–11 provides a list of these resources along with website addresses. These websites provide information useful for clinical management, research, teaching, and policy development purposes.

Patient Care Process

Patient Assessment:
- Evaluate patient’s history and symptoms to determine if substance intoxication, withdrawal, or longer-term substance use disorder are likely (see Tables 36–1, 36–3, and 36–4).
- Conduct mental (eg, Mini-Mental Status Exam) and physical examination (eg, vital signs).
- More detailed or substance-specific mental/physical examination may be required depending on presentation.

Therapy Evaluation:
- Assess medication adherence among patients receiving pharmacotherapy; substance use disorders are major risk factors for medication nonadherence.
- Assess all pharmacotherapy for effectiveness, safety, and drug interactions.

Care Plan Development:
- If substance intoxication is likely scenario:
  - Management of intoxication is typically supportive; most important goal is to maintain cardiopulmonary function. If consciousness is impaired, obtain blood chemistries to help identify causative substance and rule out other etiologies.
  - Observe patient until intoxication has resolved for safety of patient and others.
- If substance withdrawal is the likely scenario:
  - Select appropriate withdrawal severity instrument to help guide medication use (see Table 36–2).
  - Severe symptoms (eg, alcohol withdrawal seizures) should be treated in the inpatient setting.
  - Achieving long-term recovery: consider medication management as adjunct to psychosocial approaches.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Recognize signs and symptoms of schizophrenia and be able to distinguish among positive, negative, and cognitive impairments associated with the illness.
2. Explain pathophysiologic mechanisms that are thought to underlie schizophrenia.
3. Identify treatment goals for a patient with schizophrenia.
4. Recommend appropriate antipsychotic medications based on patient-specific data.
5. Compare side-effect profiles of individual antipsychotics.
6. Educate patients and families about schizophrenia, treatments, and the importance of adherence to antipsychotic treatment.
7. Describe components of a monitoring plan to assess the effectiveness and safety of antipsychotic medications.

INTRODUCTION

In most cases, schizophrenia is a devastating, chronically debilitating disorder. It may be thought of as a clinical syndrome, with many possible pathophysiological pathways that ultimately manifests with psychotic symptoms, including hallucinations, delusions, and disordered thinking. Commonly, these symptoms are accompanied by cognitive impairment (abnormalities in thinking, reasoning, attention, memory, and perception), impaired insight and judgment, and negative symptoms including loss of motivation (avolition), loss of emotional range (restricted affect), and a decrease in spontaneous speech (poverty of speech). Cognitive impairments and negative symptoms account for much of the poor social and functional outcomes. Schizophrenia is the fourth leading cause of disability among adults and is associated with substantially lower rates of employment, marriage, and independent living compared with population norms. However, earlier diagnosis, treatment, and advances in research and newer treatment developments have led to better outcomes.

EPIDEMIOLOGY AND ETIOLOGY

Approximately 1% of the world population suffers from schizophrenia, with symptoms typically presenting in late adolescence or early adulthood. Prevalence is equal in men and women, but symptoms appear earlier in men with first hospitalization typically occurring at 15 to 24 years compared to 25 to 34 years.

The etiology of schizophrenia remains unknown. A genetic basis is supported by the fact that first-degree relatives of patients with schizophrenia carry a 10% risk of developing the disorder, and when both parents have the diagnosis, the risk to their offspring is 40%. For monozygotic twins, the concordance rate is about 50%. Many genes have been weakly associated with the development of schizophrenia; however, there is probably no single “schizophrenia gene.” Research continues to explore candidate genes, loci, and copy number variants, hoping to better understand the genetic contribution. Possibly, when a genetic liability is present, environmental stimuli may trigger expression of the illness. Some data suggest intrauterine exposure to significant stress, viral or bacterial infections may be a risk factor; however, more research is needed.

PATHOPHYSIOLOGY

The dopamine hypothesis, the oldest pathophysiologic theory, proposes that psychosis is caused by excessive dopamine in the brain. This hypothesis followed the discovery that chlorpromazine, the first antipsychotic medication, was a postsynaptic dopamine antagonist. Drugs that cause an increase in dopamine (eg, cocaine and amphetamines) worsen or cause psychotic symptoms, and drugs that decrease dopamine (eg, antipsychotics) improve psychotic symptoms. However, data reveal a more complicated picture with both hyperdopaminergic and hypodopaminergic brain regions in schizophrenia. Hypodopaminergic activity in the prefrontal lobe is thought to relate to the core negative symptoms. Thus, a more modern reworking of the dopamine hypothesis is the “dysregulation hypothesis,” which takes these findings into account. It is possible, however, that the hypothesized dopamine abnormalities may represent changes occurring secondary to other pathophysiologic abnormalities. Other implicated neurotransmitter systems include a combined dysfunction of the dopamine and glutamate neurotransmitter systems. It is hypothesized that glutamate, possibly through malfunctioning N-methyl-D-aspartate (NMDA) receptors, impacts dopaminergic activity in...
A 23-year-old single man presents to the clinic with his mother an approximately 1-year history of being fearful in public and continuously hearing voices of “famous people” talking with him and giving him advice. He was psychiatrically hospitalized following an episode of hypothyroidism during his sophomore year in college. Following that, 1 year ago, he withdrew from college, as he was having difficulty concentrating, and he was struggling academically. He was employed briefly as a waiter, but he felt he was not able to concentrate there as well. He also felt that the stress of working with many people made his fears worse. He lives with his mother. His parents are divorced, and he does not see his father, as he feels fearful and harshly criticized by him. He has given consent for his mother to be involved in his treatment, and during her interview, she states that his father will be of “no use,” as he is “from a culture that doesn’t believe in mental illness.” She worries that her son spends too much time in his room and that he no longer does the activities he used to enjoy, such as listening to music and going to movies. The patient states he “doesn’t really miss” doing these things, and he doesn’t want to be pressured to do them. His mother also worries that he has strange eating habits and that his sleep is “off”—up at night and sleeping too much during the day.

What diagnoses are suggested by this presentation?
What additional information would help to clarify the diagnosis and why?
Should the patient’s parents be involved in his care?

depressive symptoms may lead to poor hygiene and impaired self-care. Sleep and appetite are often disturbed, and they often have difficulty living independently, forming close relationships with others, and initiating or maintaining employment. Comorbid medical disorders, such as type 2 diabetes and chronic obstructive pulmonary disease, are prevalent in people with schizophrenia because of sedentary lifestyles, poor dietary habits, obesity, or cigarette smoking. Approximately 60% of people with schizophrenia smoke, and approximately 50% use illicit drugs and alcohol.

CLINICAL PRESENTATION AND DIAGNOSIS

In addition to the positive, negative, and cognitive symptoms of schizophrenia, people with schizophrenia may appear uncooperative, suspicious, hostile, anxious, or aggressive. Psychotic and depressive symptoms may lead to poor hygiene and impaired self-care. Sleep and appetite are often disturbed, and they often have difficulty living independently, forming close relationships with others, and initiating or maintaining employment. Comorbid medical disorders, such as type 2 diabetes and chronic obstructive pulmonary disease, are prevalent in people with schizophrenia because of sedentary lifestyles, poor dietary habits, obesity, or cigarette smoking. Approximately 60% of people with schizophrenia smoke, and approximately 50% use illicit drugs and alcohol.

KEY CONCEPT A diagnosis of schizophrenia is made clinically because there are no psychological assessments, brain imaging, or laboratory examinations that confirm the diagnosis.

The diagnosis is made by ruling out other causes of psychosis and meeting specified diagnostic criteria. When present, a family history of mental illness supports the diagnosis. The commonly accepted diagnostic criteria for schizophrenia are from the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5) (Table 37–1).

Patients presenting with odd behaviors, illogical thought processes, fixed false beliefs, and hallucinations should be comprehensively assessed to rule out other diagnoses or contributing factors. At minimum, patients with psychosis should have a medical workup at the time of admission to rule out other diagnoses or contributing factors. Often, people with psychosis are poor historians and the gathering of collateral information is necessary. Comorbid substance abuse, medical illnesses, and psychosocial stressors, often confound the diagnosis.

COURSE AND PROGNOSIS

Treatment of schizophrenia is often associated with poor long-term outcomes, however, some people can achieve remission. Typically there are intermittent acute psychotic episodes with a downward decline in psychosocial functioning. Though many of the more dramatic and acute symptoms may fade with time, severe residual symptoms may persist. Involvement with law enforcement is fairly common for vagrancy, loitering, and disturbing the peace. Life expectancy is shortened primarily because of suicide, cardiovascular disease, accidents, and compromised self-care. Life-time risk of suicide for people with schizophrenia is 5% to 10%. Persistent compliance with a tolerable drug regimen improves prognosis, while relapse without medication exceeds 50% in the year following noncompliance.

The onset of schizophrenia can be rapid with acute psychosis presenting as the first symptom, or onset can be insidious with negative symptoms and social impairments precluding psychosis by many years. Whether insidious or acute, the period around the diagnosis is difficult for patients, families, and clinicians. Patients may hide symptoms from family and friends and isolate themselves from social support networks. Gradual development of psychosis and the misunderstanding of symptoms can delay diagnosis and treatment. Recent data suggest that people treated early in their illness may have a better prognosis. Therefore, the first challenge of optimal therapy is to initiate treatment closer to the onset of psychosis.

TREATMENT

Desired Outcomes

KEY CONCEPT The goals of treatment are to reduce symptomatology and psychotic relapses and to improve functional and social outcomes.

- Patients should receive comprehensive treatment as early as possible. In the past, the primary treatment goal was to decrease positive symptoms and associated hostile and aggressive behaviors. Newer approaches also focus on functional and social outcomes. Though antipsychotic medications may improve combative, hostility, sleep, and appetite, other aspects of the illness are less responsive to treatment. Improvements in negative symptoms, cognitive functioning, social skills, and judgment generally require adjunctive treatments and a longer period to improve.
Clinical Presentation of Schizophrenia

**General**

Schizophrenia is a chronic disorder of thought and affect, causing significantly impaired vocational and interpersonal function. Onset is usually preceded by gradual social withdrawal, diminished interests, changes in appearance and hygiene, changes in cognition, and bizarre or odd behaviors. The clinical presentation of a person with schizophrenia is extremely varied.

**Symptoms**

**Psychotic symptoms (positive symptoms):**
- Hallucinations (distortions or exaggeration of perception)
  - Most frequently auditory, can also be visual, olfactory, gustatory, and tactile.
  - Can be voices or thoughts that feel distinct from the person’s mind.
  - Voices may be threatening or commanding (eg, commanding the person to perform a particular action).
- Delusions (fixed false beliefs)
  - Beliefs despite invalidating evidence
  - May be bizarre in nature
  - Often paranoid in nature which may cause suspiciousness
- Thought disorder (illogical thought and speech)
  - Loosening of associations
  - Tangentiality
  - Thought blocking
  - Concreteness
  - Circumstantiality
  - Perseveration
  - Thinking and speech may be incomprehensible and illogical

**Negative symptoms:**
- Impoverished speech and thinking
- Lack of social drive (avolition)
- Flatness of emotional expression
- Apathy
- May be primary or occur secondarily to medication side effects, mood disorder, environmental understimulation, or demoralization
- The best strategy for differentiating primary from secondary negative symptoms is to observe for their persistence over time despite efforts at resolving the other causes

**Cognitive impairments (diminished function in the following):**
- Attention
- Processing speed
- Verbal, visual memory, and working memory
- Problem solving
- There is a loss of, on average, one standard deviation of preillness IQ, with the average IQ between 80 and 84.

**Laboratory and Other Diagnostic Assessments**

- An initial psychotic work up includes a thorough neurologic, medical and laboratory evaluation to rule out other causes
  - Electrolytes
  - Blood urea nitrogen
  - Serum creatinine
  - Urinalysis
  - Liver and thyroid function profile
  - Syphilis serology
  - Serum pregnancy test
  - Urine toxicology

**General Approach to Treatment**

The concept of recovery has become an increasingly prominent treatment goal. Treatment planning increasingly includes providing recovery-oriented services to people with schizophrenia. A range of nonpharmacologic interventions are now part of the long-term strategy to improve functioning. Implementation of evidence-based practice and prescribing behaviors, has led to the use of interventions that promote a remission or recovery attitude. Moreover, recent attempts to improve and measure patient satisfaction have fostered patient empowerment and hope. Despite these conceptual advances and treatment improvements, many patients still fail to receive comprehensive care, and long-term outcomes remain poor.

**Antipsychotic Treatment**

Historically, only first-generation antipsychotics (FGAs; typical antipsychotics) were available, but since 1990, the SGAs (ie, atypical antipsychotics) have been marketed in the United States. These agents include risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, paliperidone, iloperidone, asenapine, lurasidone, and clozapine. Clozapine, the prototype SGA, is reserved as second-line therapy because of its unusual side-effect profile (see below).

Compared with the FGAs, the SGAs are associated with a lower risk of motor side effects (tremor, stiffness, restlessness, and dyskinesia).

With the introduction of SGAs, the use of FGAs has progressively decreased, and FGAs have less than 10% market share of the antipsychotics used for schizophrenia. This decline occurred...
### Table 37–1

**Diagnostic Criteria for Schizophrenia**

A. Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be 1, 2, or 3:

1. Delusions
2. Hallucinations
3. Disorganized speech (e.g., frequent derailment or incoherence)
4. Grossly disorganized or catatonic behavior
5. Negative symptoms (i.e., diminished emotional expression or avolition)

B. For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved before onset (or when onset is in childhood or adolescence, there is a failure to achieve expected level of interpersonal, academic, or occupational functioning).

C. Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meets Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

D. Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

E. The disturbance is not attributable to the physiological effects of a substance (e.g., drug of abuse or medication) or another medical condition.

F. If there is a history of autism spectrum disorder or communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are also present for at least 1 month (or less if successfully treated).

---

### Patient Encounter, Part 2

**PPH:** The patient was seen for his first ever mental health appointment by a psychologist in his late teens, when he had family therapy with his father to address relationship issues. He has started to see that psychologist again, following his first psychiatric hospitalization. His toxicology screens have been negative for alcohol and drugs of abuse.

**PMH:** He was first psychiatrically hospitalized following an episode of hypothyroidism during his sophomore year in college, but his symptoms continued even when his thyroid disease was stabilized. He has no other medical illness, history of head trauma, or seizure disorder.

**SH:** His parents divorced in a contentious custody battle, when he was in grade school. Prior to his sophomore year in college, he had no academic or social problems. He used alcohol periodically in college but denies using since leaving college. He denies ever using marijuana or other substances of abuse. He has held several part-time jobs from the ages of 18 to 23 years, the last of which was as a waiter. He has no health insurance.

**FH:** His grandfather had an alcohol problem, and his great uncle has a history of psychiatric hospitalization, though the specific circumstances are unknown. His mother and aunt reportedly have depression.

**Mental Status Examination**

**Appearance:** Appears somewhat disheveled, dressed in dirty clothes, and hair looks like it has not been washed or brushed for several days. No abnormal movements. Poor eye contact.

**Speech:** Quiet and somewhat monotonous

**Mood:** Nervous. He denies feeling depressed, down, or blue.

**Affect:** Guarded and mildly anxious with restricted range. He denies feeling sad, guilty, hopeless, or helpless.

**Thought content:** He is an adequate historian but has a tendency to leave out detail. He hears the voices of famous Hollywood movie stars and pop music artists. Intermittently, he hears his dad’s voice saying critical things. Sometimes, he feels that others know his thoughts. He denies suicidal or homicidal thoughts.

**Thought processes:** Vague and sometimes illogical.

**Cognition:** Grossly intact.

**Insight and judgment:** Impaired at this time. He is not sure he has a mental illness, as he continues to think his problems are related to his thyroid illness.

Given this additional information, how has your differential diagnosis changed?

What medications would you consider to be first-line options, and why?

What are the goals of initial treatment?
because of the touted better side-effect profile and other possible benefits of SGAs in nonpsychotic domains of the illness. However, a large landmark study (the Clinical Antipsychotics Trials of Intervention Effectiveness; CATIE trial; n > 1400) examined the effectiveness of SGAs relative to a midpotency FGA, perphenazine. The study revealed that the FGA was equal to the SGAs for the primary endpoint of time to discontinuation of medication.14 SGAs have historically been much more expensive than the FGAs; however risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and clozapine are now available in generic formulations. In conclusion, when selecting an antipsychotic, the risk-to-benefit profile becomes fundamental and the varying side-effect profiles must be considered.

**Second-Generation (Atypical) Antipsychotics**

FGAs exert most of their effects through dopamine-receptor blockade at the dopamine, (D₃) receptor. SGAs have greater affinity for serotonin receptors than for dopamine receptors. Despite heterogeneous receptor binding, the efficacy among the SGAs is similar.14 Additionally, recent data for SGAs and FGAs (lower doses) document similar overall efficacy with an effect size for acute treatment of 0.30 to 0.60 for most antipsychotics.15 These findings have led to a modest resurgence of FGA use. Only clozapine, however, has demonstrated superior efficacy and that is in treatment-resistant patients. An important distinction of the SGAs is their lower propensity to cause extrapyramidal symptoms (EPSs) and tardive dyskinesia (TD). TD risk with SGAs is 1.5% annually in adults (less than 54 years of age) compared to approximately a 5% annual risk with FGA treatment.16

**KEY CONCEPT** The SGAs are heterogeneous with regard to side-effect profiles. Many SGAs carry an increased risk for weight gain and for the development of glucose and lipid abnormalities; therefore, careful monitoring is essential. Dosing and comparative side effects of SGA are shown in Tables 37–2 and 37–3.

- **Risperidone**

Risperidone, a benzisoxazole derivative, was the initial first-line oral SGA to become available generically. It has high binding affinity to both serotonin 5-HT₁₂ and D₂ receptors and binds to α₁ and α₂ receptors, with very little blockade of cholinergic receptors.17 Risperidone is also approved for relapse prevention and is associated with significantly lower relapse rates than long-term haloperidol treatment.18 At doses less than or equal to 6 mg/day, EPSs are low, although higher doses are associated with a greater incidence of EPS. Risperidone use causes serum prolactin elevations similar to or greater than FGAs. Elevated prolactin levels can, but do not always, lead to amenorrhea, galactorrhea, gynecomastia, and sexual dysfunction. Mild to moderate weight gain and mild elevations in serum lipids and glucose may occur. However, patients chronically treated with other antipsychotics may experience a decline in cholesterol and triglyceride levels when changed to risperidone monotherapy.14

- **Olanzapine**

Olanzapine has greater affinity for 5-HT₂A than for D₂ receptors. It also has affinity at the binding sites of D₆, D₃, 5-HT₁₉, 5-HT₂, α₁-adrenergic, muscarinic M₁, M₄, and histamine H₁ receptors.19 In the CATIE trial, olanzapine was associated with the longest time to treatment discontinuation,14 suggesting it may differ from the other SGAs in effectiveness. Olanzapine has a low rate of EPS and causes slight, transient prolactin elevations. Olanzapine causes significant weight gain across the dosage range, similar to that seen with clozapine and greater than that observed with the other SGAs. Olanzapine is also associated with hypertriglyceridemia, increased fasting glucose, and new-onset type 2 diabetes (ie, metabolic syndrome). Among the first-line SGAs, it is associated with the greatest elevations in these metabolic parameters.14

- **Quetiapine**

Quetiapine, structurally related to clozapine and olanzapine, has high affinity for 5-HT₁₂ receptors and lower affinity for D₂ and D₄ receptors. It has some affinity for α₁, α₂, and H₁ receptors but very little for muscarinic receptors. Quetiapine may be beneficial for anxiety and depression. Motor side effects and prolactin elevations are uncommon. Orthostasis occurred in 4% of subjects in clinical trials. Sedation is generally transient. Mild weight gain and minor elevations in triglycerides can occur. Use of quetiapine with agents that can prolong the QTc interval or in patients with prolonged QTc should be avoided.

- **Ziprasidone**

Ziprasidone was developed to block D₂ receptors but also to bind with greater affinity to central 5-HT₁₂ receptors. It has a binding affinity ratio of 11:1 for 5-HT₁₂/D₂ receptors. It has a relatively high affinity for 5-HT₁, 5-HT_₁₂, α₁-adrenergic, and D₂ receptors. It should be taken with food. Liability for EPS, weight gain, and lipid elevations is low but does occur. Ziprasidone causes some prolongation of the QTc interval in adults. However, overdose data and pharmacokinetic interaction data show little evidence that significant QTc prolongation occurs. Use of ziprasidone with agents that can prolong the QTc interval or in patients with existing diseases associated with prolonged QTc should be avoided.

- **Aripiprazole**

Aripiprazole is a dopamine modulator, with both antagonist and agonist activity at the D₂ receptor. It is the only D₂ partial agonist available for the treatment of schizophrenia. The goal was to have an agent that functions as an antagonist in hyperdopaminergic states and as an agonist in hypodopaminergic states. Aripiprazole is also a partial agonist at 5-HT₁₂ receptors, an antagonist at 5-HT₁₂ receptors, and has affinity for D₂ receptors. Additionally, it has moderate affinity for α₁ and H₁ receptors with no appreciable affinity for the M₁ receptor. In CYP2D6-poor metabolizers start dosing with one-half the usual dose with adjustment to clinical efficacy. Give one-quarter the usual dose if given concomitantly with a CYP3A4 inhibitor. Sedation, nausea, and vomiting are the most often seen side effects. Elevations in weight, lipids, and glucose are generally negligible, and it does not usually cause elevations in serum prolactin. In fact, patients switched to aripiprazole from other antipsychotic agents may experience decreases in prolactin.

- **Paliperidone**

Paliperidone is the 9-hydroxy (9-OH) metabolite of risperidone. The efficacy of risperidone and paliperidone are similar. Receptor binding affinity is also similar between the two agents, with paliperidone having a greater affinity at 5-HT₁₂ compared with D₂ receptors. Unlike many other antipsychotic medications, paliperidone is mostly excreted unchanged, a potential advantage in patients with liver impairment. Patients should be told to expect to see the shell of the tablet in the stool because it may not dissolve in the digestive tract.22 Side effects of paliperidone are expected to be similar to those of risperidone, including the potential for dose-related EPS and prolactin elevation.

*aOutside product labeling guidelines.

IM, intramuscular.
Iloperidone is indicated for acute treatment of adults with schizophrenia. It exhibits high affinity for 5HT\textsubscript{2A} dopamine D\textsubscript{2} and D\textsubscript{4} receptors and acts as an antagonist at these, as well as at the 5HT\textsubscript{2A}, and norepinephrine \(\alpha_{1c}/\alpha_{2c}\) receptors. Doses must be titrated because of the risk of orthostatic hypotension, and dosing should be reduced by half in CYP2D6 poor metabolizers. Common adverse reactions include dizziness, dry mouth, fatigue, orthostatic hypotension, tachycardia, and weight gain. Dizziness, tachycardia, and weight gain were twice as common with higher dose (20–24 mg total daily dose) versus lower doses (10–16 mg total daily dose). Use of iloperidone with agents that can prolong the QTc interval or in patients with diseases that are associated with prolonged QTc should be avoided.

Asenapine is approved for the acute treatment of schizophrenia in adults. Its mechanism of action is thought to be its antagonistic activity at 5HT\textsubscript{2A} and D\textsubscript{2} receptors. It also exhibits a high affinity for other serotoninergic and dopaminergic receptors, as well as \(\alpha_{1c}\) and \(\alpha_{1d}\)-adrenergic receptors and H\textsubscript{1}-receptors. Asenapine tablets must be placed under the tongue and allowed to dissolve completely; tablets should not be chewed or swallowed. Patients should not drink or eat for 10 minutes after administration. No added benefit was seen with doses above 10 mg twice daily, but adverse effects increase. Common adverse effects include somnolence, dizziness, and akathisia. It has shown little effect on metabolic parameters and weight change. Labeling for asenapine was modified to address rare occurrence of hypersensitivity reactions, including anaphylaxis and angioedema.

Lurasidone antagonizes D\textsubscript{3} and 5HT\textsubscript{2A} receptors. It also has moderate affinity as an antagonist at \(\alpha_{1c}\) is a partial agonist at 5HT\textsubscript{1A}, and is an antagonist at \(\alpha_{1a}\)-receptors. Lurasidone should be taken with food. Adverse reactions reported in at least 5% of patients (and at least twice the placebo rate) include somnolence, akathisia, nausea, parkinsonism, and agitation. Lurasidone has shown only a small effect on body weight and causes minimal changes in other metabolic parameters.

First-Generation (Typical) Antipsychotics

The FGAs are high-affinity D\textsubscript{2}-receptor antagonists. During chronic treatment, they block 65% to 80% of D\textsubscript{2} receptors in the striatum and other dopamine tracts in the brain. Clinical response is generally associated with 60% D\textsubscript{2}-receptor blockade, while 70% and 80% are associated with hyperprolactinemia and EPS, respectively. During the 1990s, SGAs began to replace FGAs as first-line therapy.

Doses for FGAs are frequently given as **chlorpromazine equivalents**, which are defined as the FGA equipotent dose with 100 mg of chlorpromazine. The target dose recommendation for acute psychosis is 400 to 600 chlorpromazine equivalents unless the patient’s history indicates that dose may not be tolerated. Generally, maintenance therapy is 300 to 600 chlorpromazine equivalents daily. Dosing and available dosage forms are shown in Table 37–4. All FGAs are equally efficacious when studied in equipotent doses in groups of patients. However, an individual patient may not respond equally to each antipsychotic. Selection of a particular antipsychotic is based on patient variables, such as the need to avoid certain side effects or drug–drug interactions or previous patient or family history of response.

**Decanoates**

Long-acting, depot preparations are available for two FGAs (fluphenazine decanoate and haloperidol decanoate) in the United States. These compounds are esterified antipsychotics in sesame seed oil for deep intramuscular (IM) injection. Patients should be exposed to the oral form of the drug first to ensure tolerability. With initial dosing of haloperidol decanoate, concomitant oral supplementation may be temporarily necessary while the drug accumulates, as steady state is achieved after four to five dosing intervals. Fluphenazine decanoate is dosed at 1- to 3-week intervals, but haloperidol decanoate is usually dosed once a month. Conversion from oral to depot dosing and maintenance dosing recommendations are shown in Table 37–5. Generally, 12.5 mg (0.5 mL) of fluphenazine decanoate given every 2 weeks is approximately equivalent to 10 mg/day of fluphenazine orally. A maintenance haloperidol decanoate dose of 150 mg every 4 weeks is approximately equivalent to 10 mg/day of oral haloperidol. Initial decanoate injections should be preceded by a small test dose.

**Side Effects of the First-Generation Antipsychotics**

In general, the low-potency FGA agents are less likely to cause EPS than the high-potency agents. (See Table 37–4) Of note, high potency and midpotency agents may cause less EPS than once believed and were similar to SGAs in the CATIE trial.14

The FGAs are commonly associated with EPS (including akathisia [motor or subjective restlessness], dystonia [muscle spasm], and pseudoparkinsonism [akinesia, tremor, and rigidity]) caused by dopamine antagonism in the nigrostriatal pathways. Akathisia, the most common motor side effect of FGAs occurs in 20% to 40% of people. Roughly half of the cases of akathisia present within 1 month of antipsychotic initiation, though it may present within 5 to 10 days after the first dose or after an increase in dosage. Younger people and those taking high doses of high-potency antipsychotics are at greater risk for development of akathisia.

Acute dystonic reactions are abrupt in onset and are usually seen within 24 to 96 hours after a first dose or increase in dosage. Characteristic signs and symptoms include abnormal positioning or spasm of the muscles of the head, neck, limbs, or trunk. Dystonia may occur in 10% to 20% of patients. There is higher risk for dystonia in young male patients and those taking high-potency FGAs.

Pseudoparkinsonism may be present in 30% to 60% of people treated with FGAs. The onset of symptoms is usually within 1 to 2 weeks after dose initiation or dose increase. Risk factors include older age, female gender, high doses, and possibly those with depressive symptoms.26

TD is a movement disorder characterized by abnormal choreiform (rapid, objectively purposeless, irregular, and spontaneous) and athetoid (slow and irregular) movements beginning late in relation to initiation of antipsychotic therapy. It usually develops over several months or after at least 3 months of cumulative exposure to antipsychotics. Severity can range from mild and barely noticeable to severe, causing interference with ambulation. Visible TD symptoms may stigmatize persons taking antipsychotics. The estimated average prevalence of TD is 20% in patients given FGAs with a range of 13% to 36%. The incidence of new cases per treatment year with FGAs is approximately 5%.27 TD is reversible in one-third to half of cases with the cessation of the antipsychotic.28 When antipsychotics are tapered or discontinued, there is typically an transient worsening of abnormal movements. Risk factors for TD include older age; longer duration of antipsychotic treatment; and presence of EPS, substance abuse, and mood disturbances.

IM, intramuscular; SC, subcutaneous.

Disorders. SGAs have a lower risk of TD than FGAs. New-onset TD incidence is approximately 0.8% per year with SGA treatment versus 5.4% per year for FGAs. A subsequent review of studies reports a smaller difference in incidence of TD between agents (3.9% for SGAs and 5.5% for FGAs).

Neuroleptic malignant syndrome (NMS), a life-threatening emergency characterized by severe muscular rigidity, autonomic instability, and altered consciousness, can occur uncommonly with all FGAs and may also occur with SGAs. Rapid dose escalation, use of high-potency FGAs at higher doses, and younger patients have a higher risk of NMS. When NMS is diagnosed or suspected, antipsychotics should be discontinued and supportive, symptomatic treatment begun (eg, antipyretics, cooling blanket, intravenous fluids, oxygen, monitoring of liver enzymes, and complete blood cell count). Dopamine agonists (eg, bromocriptine) should be considered in moderate to severe cases.

Dermatologic side effects, photosensitivity, and cataracts may occur with the phenothiazine FGAs. Sedation is mediated by H₁-receptor antagonism; anticholinergic side effects (constipation, blurred vision, dry mouth, and urinary retention) are caused from M₁-receptor antagonism; and α₁-receptor blockade is associated with orthostatic hypotension and tachycardia (Table 37–6). QTc prolongation may occur with the lower potency FGAs, and thioridazine has a black-box warning for QTc prolongation.

Treatment Guidelines and Algorithms

A widely accepted treatment algorithm in the United States is the Texas Implementation of Medication Algorithms (TIMA), developed by a national panel of experts and updated in 2008. Algorithms go beyond guidelines, providing a framework for clinical decision making. According to the TIMA schizophrenia algorithm, the SGAs (except clozapine) should be used as first-line treatment. Choice of SGA is guided by side-effect profiles and patient clinical characteristics. Treatment with a given drug should be continued for 4 to 6 weeks to assess response. If only partial response or nonresponse is noted, a trial of a second SGA should be initiated (Figure 37–1). Other similar guidelines include the APA Practice Guidelines for Schizophrenia, the Expert Consensus Guideline Series, and the 2009 Schizophrenia Patient Outcomes Research Team (PORT) Treatment Recommendations. In contrast to the TIMA guidelines, the PORT recommends use of either FGAs or SGAs as first-line therapy.

Treatment Adherence

Estimates of nonadherence to antipsychotics range from approximately 24% to 88% with a mean of approximately 50%. Subjects who are nonadherent have about a fourfold greater risk of a relapse than those who are adherent. Neurocognitive deficits and paranoid symptoms may hamper adherence, and identification of nonadherence by caretakers and providers can be challenging. Antipsychotic side effects such as EPS, weight gain, and sexual dysfunction are also major contributing factors to treatment nonadherence. Other factors include delusions, substance abuse, and negative symptoms. For patients who have relapsed several times because of nonadherence, have a history of dangerous behavior, or risk a significant loss of social or vocational gains when relapsed, treatment with long-acting formulations should be encouraged. Risperidone, paliperidone, olanzapine, and aripiprazole are available as long-acting injectable formulations. In general, oral tolerability of these agents should be ensured prior to initiating long-acting injection. Dosing and other information about these formulations is shown in Table 37–5.

Special Populations

Dosing in Renal and Hepatic Impairment

Table 37–7 shows dosing guidance on specific antipsychotic medications.

Children and Adolescents

Around 10% to 30% of patients with schizophrenia have psychotic symptoms before their 18th birthday. The diagnosis of schizophrenia in children and adolescents is often challenging, and the differential diagnosis includes autistic spectrum disorders, attention-deficit/hyperactivity disorder, and language or communication disorders. The existence of prominent hallucinations or delusions helps make the diagnosis because they are not prominent in other disorders. Fifty-four percent to 90% of patients developing schizophrenia before age 18 years have premorbid abnormalities such as withdrawal, odd traits, and isolation.

Treatment for psychotic children and adolescents ideally is intensive, comprehensive, and structured. Day treatment, hospitalization, or long-term residential treatment may be necessary. Pharmacologic treatment is indicated if psychotic symptoms cause significant impairments or interfere with other interventions. Children and adolescents are more vulnerable to EPS, particularly dystonias, than are adults. Because of concerns about EPS and TD in children and adolescents, it is recommended that antipsychotic therapy be initiated with SGAs. Aripiprazole, risperidone, quetiapine, olanzapine, and paliperidone are approved by the Food and Drug Administration (FDA) for the treatment of schizophrenia in pediatric and adolescent populations. Initiation and target dosing is lower for adolescents than adults.

Agents with significant sedative and anticholinergic side effects are not preferred because they can interfere with thinking, thus impairing school performance. Compared with adults, children and adolescents tend to gain more weight when taking these agents. Young patients should be started on lower doses than adults and should be titrated at a slower rate. Side effects should be monitored closely initially and throughout therapy.

Elderly

Psychotic symptoms in late life (after 65 years of age) generally result from an ongoing chronic illness; however, a small
percentage of patients develop psychotic symptoms de novo, defined as late-life schizophrenia. However, other illnesses with psychotic symptoms are common in this population; approximately one-third of patients with Alzheimer disease, Parkinson disease, and vascular dementia experience psychotic symptoms.

Antipsychotics can be safe and effective for the treatment of schizophrenia in the elderly, if used at lower doses than those commonly used in younger adults. Older adults are particularly vulnerable to the side effects of the FGAs. Pseudoparkinsonism reportedly occurs in more than 50% of elderly patients receiving these agents, and the cumulative annual incidence of TD in middle-aged and elderly patients is greater than 25%. Limited data suggest the risk of TD to be approximately 4% with the SGA and the likelihood of reversing this condition diminishes with age.53

Orthostasis, estimated to occur in 5% to 30% of geriatric patients, is a major contributing factor to falls that often lead to injuries and loss of independence. Low-potency antipsychotics and clozapine are more likely to cause significant orthostasis. Antipsychotics may cause or worsen anticholinergic effects, including constipation, dry mouth, urinary retention, and cognitive impairment. Greater antipsychotic-associated impairment

FIGURE 37–1. Texas Implementation of Medication Algorithms (TIMA) algorithm for antipsychotic treatment in schizophrenia. Choice of antipsychotic should be guided by considering the clinical characteristics of the patient and the efficacy and side-effect profiles of the medication. Any stage may be skipped depending on the clinical picture or history of antipsychotic failures. (ECT, electroconvulsive therapy; FGA, first-generation antipsychotic; SGA, second-generation antipsychotic.) (Adapted from the Texas Department of State Health Services, with permission.)

(Continued)
in cognitive functioning may occur in the elderly compared to younger adults. In the elderly, this can lead to decreased independence, a very problematic issue. As a result of data showing a statistically significant increase in mortality in elderly dementia patients taking SGAs, a black-box warning was added to the manufacturer’s information for all antipsychotics. Patients and families should be informed of this risk before using these agents in patients with dementia. Dosing in the elderly is initiated lower, and titration is slower than in younger adults. Maximum doses are often half of adult doses (see Table 37–7).

▶ **Dually Diagnosed Patients**

Estimates of the proportion of schizophrenia patients abusing alcohol and/or illicit drugs range from 40% to 60%. Generally, the most common drugs of abuse are cannabis, cocaine, and alcohol. Substance use often worsens the clinical course and complicates treatment. Dually diagnosed patients are more likely to be nonadherent with treatment. They have a poorer response rate to the FGAs, more severe psychosis, and higher rates of relapse and rehospitalization than patients who are not abusing substances. EPS may occur more frequently in substance-abusing patients, and alcohol use is a risk factor for developing TD. SGAs are effective in this population, and they may cause a reduction in the use of drugs and alcohol.

▶ **Treatment-Resistant Patients**

For 20% to 30% of people with schizophrenia, drug treatment is ineffective. A standard definition of treatment resistance is persistent positive symptoms despite treatment with at least two different antipsychotics given at adequate doses (a dose equivalent to at least 600 mg of chlorpromazine) for an adequate duration (4–6 weeks). In addition, patients must have a moderately severe illness as defined by rating instruments, and have a persistence of illness for at least 5 years. These patients are often highly symptomatic and require extensive periods of hospitalization.

**Clozapine** Clozapine remains the only drug with proven superior efficacy in treatment-resistant patients, and it is the only drug approved for treatment-resistant schizophrenia, with response rates of 30% to 50% in treatment-resistant patients. It is efficacious after nonresponse to other SGAs, in partially responsive patients and patients who have had a poor response to other medication for years. According to published guidelines and recommendations, clozapine should be considered after two failed antipsychotic trials but may be considered sooner if the individual patient situation warrants. Additionally, it has a beneficial effect for aggression and suicidality and is FDA approved for treatment of suicidal behavior in people with psychosis

It is unknown which pharmacologic properties account for clozapine’s superior efficacy. Clozapine has a low affinity for D₂ receptors, blocks D₂ receptors, and is a 5-HT₁₂ antagonist. Clozapine’s use is limited by the regulatory requirements resulting from the risk for agranulocytosis (0.86%–1% of patients), which is a rare but potentially life-threatening side effect. The required long-term hematologic monitoring (Table 37–8) can be a barrier for both patients and care providers. Other rare side effects include seizures and myocarditis. Other common unpleasant side effects include sedation, dizziness, constipation, enuresis, weight gain, and hypersalivation.

The optimal plasma level of clozapine is a minimum trough level of 300 to 350 ng/mL (300–350 mcg/L; 0.92–1.07 μmol/L; or 918–1071 nmol/L), usually corresponding to a daily dose of 200 to 400 mg, although dosage must be individualized. Males and smokers tend to require higher doses to achieve the targeted blood level due to more rapid metabolism.

**Acutely Psychotic Patients**

Psychiatric emergencies occur in emergency departments, psychiatric units, medical facilities, and outpatient settings. Although verbal interventions are recommended as initial management, most psychiatric emergencies require both pharmacologic and psychological interventions. Safe and effective IM formulations are available for a number of FGAs and three SGAs (aripiprazole, ziprasidone, and olanzapine). These IM SGAs are now recommended as first-line therapy in agitated schizophrenia patients; however, IM benzodiazepines, most often lorazepam with or without concomitant oral antipsychotics are also used. Concomitant IM olanzapine and benzodiazepines may cause cardiorespiratory depression and should be avoided if possible. High doses of FGAs, termed *rapid neuroleptization*, are no longer recommended.

**Patient Encounter, Part 4**

He is initially reluctant to get “a shot” but finally agrees, as he also does not want to get into power struggles with his mother about whether or not he is taking his medication. His clinician encourages him to exercise regularly and eat a healthy diet that is low in carbohydrates.

Over the next several months, he is more stable on the long-acting intramuscular form of risperidone, and he has not gained further weight. His eating habits are normal. He is less anxious, and his sleep is better. He is still, at times, preoccupied with the “Hollywood stars,” and at times, the voice he hears of his father is upsetting to him, particularly when he is falling asleep at night. After 6 months of treatment, his clinician notices slight mouth movements that could be early tardive dyskinesia. After discussion of the risks and benefits, the patient agrees to a trial of clozapine. In a separate phone call to his mom, his clinician reviews the pros and cons of the clozapine trial.

*Why is his clinician considering a clozapine trial?*

*What are the rare serious side effects of clozapine versus the common manageable side effects?*
and certain FGA agents may be preferred in drug-naïve pregnant patients because of availability of more reproductive safety data. If pregnancy occurs during antipsychotic treatment, however, continuation of previous therapy is preferred. On the basis of available data, each case should be weighed individually.

A labeling change for antipsychotic medications has been implemented by the FDA to address the potential risk for EPS and symptoms of withdrawal in newborns whose mothers were treated with antipsychotics in the third trimester. Withdrawal symptoms may include agitation, abnormal muscle tone (increased or decreased), tremor, sleepiness, and difficulty in breathing or feeding, which may last for hours to days after delivery. In some newborns, specific treatment for withdrawal is not needed, whereas in others, longer hospital stays may be required.

Although SGAs are excreted in breast milk, most case reports document a low frequency of deleterious effects on the infant. Women taking prolactin-sparing SGAs (SGAs other than risperidone and paliperidone) may have enhanced fertility compared with women taking other antipsychotics because they are less likely to be anovulatory. Therefore, women of childbearing potential taking antipsychotics must be educated about birth control.

**Pharmacokinetics**

All antipsychotics, are at least to some extent, metabolized by hepatic CYP450 metabolic enzymes to water-soluble compounds that are excreted by the kidneys (Table 37–9). Unlike the other antipsychotics, ziprasidone is mostly metabolized by aldehyde oxidase, a metabolic system independent of the CYP450 system. Paliperidone, the 9-OH metabolite of risperidone, is mostly excreted unchanged in the urine, although up to one-third may be metabolized. The transmembrane energy-dependent efflux transporter P-glycoprotein may limit the ability of drugs to penetrate the blood–brain barrier and therefore impact pharmacologic activity in the brain. Antipsychotics currently known to use this pathway include perphenazine, haloperidol, fluoxetine, quetiapine, risperidone, and olanzapine.

Additive side effects may occur with combined drug therapies, and a few clinically significant drug interactions are notable (see Table 37–9). Cigarette smoking decreases serum concentrations of clozapine and olanzapine by induction of CYP1A2. Although antipsychotics are highly protein bound, protein-binding interactions are generally not clinically significant. Absorption of most antipsychotics is not affected by food, with the exception of lurasidone and ziprasidone. The mean maximum concentration of lurasidone increases threefold when administered with food, and ziprasidone’s absorption is increased by 60% to 70% when given with meals.

Ziprasidone, iloperidone, and quetiapine have potential to prolong the QTc interval. Using them with other agents that prolong the QTc interval should be undertaken with caution. These other agents include, but are not limited to, quinidine, sotalol, chlorpromazine, droperidol, mesoridazine, pimozide, thioridazine, gatifloxacin, halofantrine, mefloquine, moxifloxacin, and pentamidine. Combining higher doses of ziprasidone, iloperidone or quetiapine with ketoconazole or erythromycin should be undertaken cautiously.

CYP450, cytochrome P450 isoenzyme.

Pathways: CYP 1A2, 2E1, CYP 3A4, CYP 2D6; Other metabolic pathways: Glucuronidation by UGT1A4.

Concentrations: Increase (increase antipsychotic concentrations), Decrease (decrease antipsychotic concentrations).
Added pharmacodynamic effects are possible when combining antipsychotics with other drugs that can cause sedation, hypotension, anticholinergic symptoms, and weight gain or metabolic abnormalities.

**Adjunct Treatments**

The judicious use of pharmacologic therapies other than antipsychotics is often necessary for the treatment of motor side effects, anxiety, depression, mood elevation, and possibly residual psychotic symptoms. Anticholinergic medications (eg, benztpine, 1 to 2 mg two times daily; trihexyphenidyl, 1 to 3 mg three times daily; and diphenhydramine, 25 to 50 mg two times daily) are used to treat EPS. They may be prescribed prophylactically with high-D₂-binding agents or in patients at risk for EPS or for treatment of EPS. β-Blockers (eg, propranolol 30–120 mg/day) are sometimes effective for patients who develop akathisia. In some situations, such as on an inpatient unit, the concomitant use of benzodiazepines (eg, lorazepam 1–3 mg/day) with the SGAs may be necessary for agitation or insomnia.

Antidepressants may be useful for patients with schizophrenia who have depressive symptoms. Because suicide and depression are linked, aggressive treatment is necessary when depression is present. The selective serotonin reuptake inhibitors (SSRIs) are the preferred agents, but they may inhibit the CYP450 enzymes, thus raising plasma concentrations of clozapine, olanzapine, and haloperidol. Mood stabilizers, such as lithium and the anticonvulsants, have long been used adjunctively with the antipsychotics to treat the affective component of schizoaffective disorder.

Approximately 30% of treatment-resistant patients given clozapine do not respond, and another 30% have only a partial response. Limited treatment options are available for these patients. A number of augmentation strategies have been tried, including FGAs, SGAs, mood stabilizers (eg, lithium, valproate, and topiramate), minocycline, antidepressants, transcranial magnetic stimulation (TMS) and electroconvulsive therapy (ECT). Though controlled trial results are mixed, some data support the adjunctive use of risperidone, lamotrigine, or aripiprazole in clozapine-treated patients.

**Psychosocial Treatment**

**KEY CONCEPT** Psychosocial support helps improve functional outcomes. Residual symptoms often persist such as avolition, isolation, and impaired social functioning, limiting participation in social, vocational, and educational endeavors. Psychosocial interventions, as adjuncts to pharmacotherapy, are designed to improve psychosocial functioning, self-esteem, and life satisfaction. These treatments are mainly used as targeted treatments for social and cognitive impairments. In the United States, psychosocial treatments are less standardized than in Europe, but their use is on the rise. There are much data to support family education in decreasing relapse rates and vocational support to improve vocational outcomes. A few of the best-supported and most promising approaches to psychosocial rehabilitation are social skills training (SST), cognitive behavioral therapy (CBT), acceptance commitment therapy, and cognitive remediation (CR). In addition, Assertive Community Treatment (ACT) and Medical Home care models may improve outcomes.

**Patient Education**

**KEY CONCEPT** Education of the patient and family regarding the benefits and risks of antipsychotic medications and the importance of treatment adherence must be ongoing and integrated into pharmacologic management. Medication management discussions offer an opportunity to provide illness and treatment education including the nature and course of schizophrenia, and can serve as a time to hear the patient’s life goals. Key considerations include:

- Involve families in the education and treatment plans because family psychoeducation may decrease relapse, improve symptomatology, and enhance psychosocial and family outcomes.
- Be clear that there is no cure for schizophrenia and that medication can be effective to decrease and improve many symptoms.
- Explain common and rare but dangerous side effects.
- Stress the importance of medication and treatment adherence for improving long-term outcomes.
- Decision making on the best course of treatment should be a shared process.

**OUTCOME EVALUATION**

Developing a good working alliance with the patient is essential. In the absence of a solid therapeutic relationship, patients are frequently reluctant to share their beliefs, personal experiences, and life goals.

**Symptom Monitoring**

Many assessments are available to objectively rate positive and negative symptoms, level of function, and life satisfaction. The most commonly used scales include:

- Positive and Negative Symptom Scale (PANSS)
- Brief Psychiatric Rating Scale (BPRS)
- Clinical Global Impression (CGI) Scale

Using these scales on a regular basis, particularly when switching medications or changing doses, is a more reliable means of monitoring symptoms. Symptom assessments cannot capture the full range of possible improvements, but they can be useful in deciding whether a medication is having substantial benefit.

**Side-Effect Monitoring**

**KEY CONCEPT** Regularly monitor for side effects and overall health status. Perform orthostatic blood pressure measurements before initiating antipsychotics and regularly throughout treatment. Ask about impaired menstruation, libido, and sexual performance.
Patient Care Process

Patient Assessment:
- Review the patient’s chief complaint, presenting symptoms, and history, including family psychiatric history. Assess organization of thoughts and range of affect. Assess presence of mood disturbance, likelihood of harm to self or others, and presence of hallucination, paranoia and/or delusions of control.
- Assess medical records, including laboratory and imaging studies, to rule out medical causes of psychosis.
- Obtain collateral information from family, past medical records and other providers to help clarify the history.
- Elicit the patient’s housing arrangements, social and vocational goals.

Therapy Evaluation:
- Assess current treatments and outcomes of prior treatments.
- Select an antipsychotic based on the side-effect profile that is most appropriate and acceptable to the patient.
- Consider collaboration with other professionals or family members.
- Consider how income and insurance coverage might influence pharmacotherapy choice.

Care Plan Development:
- Collaboratively, develop a treatment plan that addresses medication adherence and healthy lifestyle goals, including substance and cigarette use.
- Communicate that treatment plan adherence will enhance the likelihood of meeting goals.
- Devise a plan to optimize compliance.
- Educate the patient and, with patient consent, their family about the illness, medication treatments, possible side effects, and goals of treatment.
- Enlist adjunctive treatments, including psychosocial therapies to optimize outcomes.

Follow-up Evaluation:
- Schedule appointments more frequently initially to assess effectiveness, adverse drug reactions, drug interactions, and allergies.
- Assess the need for adjunctive therapies to enhance progress toward goals.
- Monitor appropriate laboratory measures to prevent or minimize adverse effects, including metabolic abnormalities.
- Assess for emergence of new target symptoms.
- Optimize dosing and consider clozapine if criteria are met for treatment resistance.

regularly. Encourage patients to have annual eye examinations because several antipsychotic medications have been associated with the premature development of cataracts. At baseline check body weight, fasting glucose, glycated hemoglobin, and lipid profile, and repeat these measurements 4 months after initiation of medication and then yearly. For patients at higher risk of developing diabetes and those who gain weight, check body weight more often (Table 37–10). Perform baseline electrocardiography for patients with preexisting cardiovascular disease or risk for arrhythmia. With clozapine therapy, there is a risk for the development of agranulocytosis, which is greatest in the first 6 months of treatment. Required monitoring of white blood cell counts is described in Table 37–8.

Commonly used rating scales to monitor for EPS include the Simpson Angus Scale (SAS) and the Extrapyramidal Symptom Rating Scale (ESRS). Akathisia is commonly monitored by the Barnes Akathisia Scale (BAS). The emergence of dyskinesias could represent the emergence of TD. Monitor patients on SGAs for TD at least annually, and patients taking FGAs at each visit. The most commonly used instrument to measure these symptoms is the Abnormal Involuntary Movement Scale (AIMS).

LEARNING OBJECTIVES

Upon completion of this chapter, the reader will be able to:

1. Explain the etiology and pathophysiology of major depressive disorder (MDD).
2. Identify the signs and symptoms of MDD.
3. Outline the treatment goals for a patient with MDD.
4. Recommend pharmacotherapy given a specific patient with MDD.
5. Develop a monitoring plan for a specific patient with MDD which includes the assessment of efficacy as well as toxicity.
6. Predict, prevent, identify, and resolve potential drug-related problems.
7. Educate patients and caregivers on the proper use of antidepressant therapy.

INTRODUCTION

Major depression is a common, seriously disabling, disorder nonresponsive to volitional efforts to feel better. Individuals with major depressive disorder (MDD) experience pervasive symptoms affecting mood, thinking, physical health, work, and relationships. Suicide often results when MDD is inadequately diagnosed and treated. Over and under detection of MDD is an important consideration. Primary care providers have become increasingly involved in the management of MDD. Studies show that over detection of MDD can outnumber missed cases. Antidepressants account for 15 of the top 200 prescriptions drugs dispensed in the United States. Inadequate treatment remains a serious concern.

EPIDEMIOLOGY AND ETIOLOGY

The lifetime and 12-month prevalence estimates for MDD are 16.2% and 6.6%, respectively. Women are twice as likely as men to experience MDD. The average age of onset is in the mid-twenties; many patients with MDD have comorbid psychiatric disorders, especially anxiety and substance abuse disorders.

According to the World Health Organization (WHO), depression is the leading cause of disability (based on years lived with disability) and the fourth leading cause of the global burden of disease.

Symptoms of depression are due to a change in the brain neurotransmitters, norepinephrine (NE), serotonin (5-HT), and dopamine (DA).

PATHOPHYSIOLOGY

The cause of MDD is unknown but is probably multifactorial. Multiple theories abound, and practitioners suggest that development of depression likely involves a complex interaction of genetic predisposition, psychological stressors, and underlying pathophysiology. There are no currently accepted unifying theories to adequately explain the pathophysiology of depression.

Genetics

First-degree relatives of MDD patients are about three times more likely to develop MDD compared with controls. Adoption and twin studies also suggest aggregation of MDD is due to genetic influences. Major depression has been associated with four different genes. They include polymorphisms in the glucocorticoid receptor gene NR3C1, the monoamine oxidase A gene, the gene for glycogen synthase kinase-3β, and a group-2 metabotropic glutamate receptor gene (GRM3).
Stress
Major life stressors do not always cause depression. Nevertheless, there is an undeniable association between life stressors and depression, and there appears to be a significant causative interaction between life stressors and genetic predisposition. Although acute stressors may precipitate depression, chronic stressors cause longer episodes and are more likely to lead to relapse and recurrence.9

Biogenic Amine and Receptor Hypotheses
**KEY CONCEPT** The primary hypothesis is the biogenic amine hypothesis which states that a deficit of NE, DA, or 5-HT at the synapse is the cause of depression. Support for this hypothesis is that existing antidepressants increase synaptic monoamine concentrations (see Pharmacologic Therapy). One argument against this hypothesis is that patients with depression do not always have decreased monoamine levels. Additionally, monoamine levels are altered within hours of initiating antidepressant therapy, but response is delayed by 2 to 4 weeks or more.

The receptor hypothesis suggests that depression is related to abnormal functioning of neurotransmitter receptors. In this hypothesis, chronic administration of antidepressants alters receptor sensitivity causing desensitization or down regulation of β-adrenergic and 5-HT receptors leading to therapeutic response. Importantly, the time required for changes in receptor sensitivity correlates with antidepressant onset.9 These hypotheses are clearly oversimplifications of the pathophysiology of depression. MDD probably involves a complex dysregulation of monoamine systems that modulate and are modulated by other neurobiological systems.

Other Neurobiological Hypotheses
At least three categories of peripheral hormones are associated with the pathophysiology of depression. They include (1) neurotrophic and other growth factors including brain derived neurotrophic factor (BDNF), vascular endothelial growth factor (VEGF), and insulin-like growth factor, (2) proinflammatory cytokines including interleukin-1β, interleukin-6, and tumor necrosis factor-α; and (3) the hypothalamic pituitary axis (HPA).8

Proinflammatory cytokines are increased in individuals with MDD, and antidepressants suppress the synthesis of these cytokines. HPA axis regulation is impaired in depression, and antidepressants can attenuate the neuroendocrine response. BDNF is decreased in patients with MDD, and antidepressants reverse this response.8

**CLINICAL PRESENTATION AND DIAGNOSIS**
The diagnosis of a major depressive episode (MDE) requires the presence of five depressive symptoms for a minimum of 2 weeks that cause clinically significant effects.5 The diagnosis of MDD is based on the presence of one or more MDEs during a person’s lifetime (Table 38–1).5

Differential Diagnosis
MDEs also occur in bipolar disorder. Individuals with bipolar disorder also experience hypomanic, manic, or mixed episodes (see Chapter 39) during the course of their illness, but individuals with MDD do not.5

The anxiety, personality, and substance use disorders are frequently associated with MDD. Several chronic medical conditions have strong correlations with MDD. MDD is associated with a 65% increased risk of diabetes in elderly patients.11 MDD is also strongly correlated with coronary artery disease. Other medical disorders associated with depression include hypothyroidism, cancer, anemia, infections, electrolyte disturbances, folate deficiency, neurologic disorders, and cardiovascular and respiratory disease.5 Identification and treatment of MDD in patients with chronic medical conditions is important. Inadequate recognition and treatment of depression may increase the mortality associated with these medical disorders.11 Use of central nervous system (CNS) depressants such as alcohol, benzodiazepines, or narcotics, is associated with an increased incidence of depression.12 Some drugs that cause depressive symptoms include corticosteroids, contraceptives, leviteracetam, topiramate, vigabatrin, gonadotropin-releasing hormone agonists, interferon-α, interleukin-2, varenicline, meloxicam, isotretinoin, propranolol, clonidine, methyldopa, reserpine, and sotalol.13

Persistent depressive disorder (dysthymia) is a chronic form of depression that must be differentiated from MDD. Many symptoms of dysthymia are similar to those of MDD, but they are chronic and milder. Symptoms must be present for at least 2 years and may include sleep and appetite disturbances, lack of energy, poor self-image, and difficulty making decisions. Individuals with dysthymia are more likely to develop MDD than the general population, and when this occurs it is called “double depression.”4

**COURSE AND PROGNOSIS**
Symptoms of a major depressive episode usually develop gradually over days to weeks, but mild depressive and anxiety symptoms may last weeks to months before onset of the full syndrome. Untreated, MDEs last 6 months or more, but a minority of

</tbody>
</table>

aOne of these two symptoms must be present.

individuals experience chronic episodes that last at least 2 years. Approximately two-thirds of patients recover and return to normal mood, but one-third have only a partial remission.

The course of MDD varies markedly between patients. It is not uncommon for a patient to experience only a single MDE, but most patients with MDD experience multiple episodes. The number of prior episodes predicts the likelihood of developing subsequent episodes. A patient experiencing a third MDE has a 90% chance of having a fourth one. MDD has a high mortality rate because approximately 15% of patients ultimately complete suicide.

**TREATMENT**

**Desired Outcomes**

- The goal of therapy for patients with MDD is resolution of depressive symptoms, return to euhymia, and prevention of relapse and recurrence of symptoms. **[Key Concept]** One extremely important goal is prevention of suicide attempts. Other desired outcomes include improving quality of life including normalization of functioning in areas such as work and relationships, minimization of adverse effects, and reduction of health care costs.

**Nonpharmacologic Therapy**

Evidence supports efficacy of interpersonal and cognitive-behavioral therapy in the treatment of MDD. Psychotherapy alone is an initial treatment option for mild to moderate depression, and it may be useful combined with pharmacotherapy for the treatment of severe depression. This combination can be more effective than either treatment alone in severe or recurrent MDD. Combination treatment may be helpful for patients with psychosocial stressors, interpersonal difficulties, or comorbid personality disorders.

Electroconvulsive therapy (ECT) is a highly efficacious and safe treatment alternative for MDD. The response rate is about 80% to 90%, and it exceeds 50% for patients who have failed pharmacotherapy. ECT may be beneficial for MDD that is complicated with psychotic features, severe suicidality, refusal to eat, pregnancy, or contraindication to pharmacotherapy. Six to 12 treatments are typically necessary with response occurring in 10 to 14 days. When ECT is discontinued, antidepressants are initiated to help maintain response. Side effects after ECT include temporary confusion, retrograde and anterograde amnesia.

Light therapy is an alternative treatment for depression associated with seasonal (e.g., winter) exacerbations. Side effects include eye strain, headache, insomnia, and hypomania.

Vagus nerve stimulation (VNS), which was approved by the Food and Drug Administration (FDA) in 2005, may be used for treatment-resistant depression. A pulse generator is surgically implanted under the skin of the left chest, and an electrical lead connects the generator to the left vagus nerve which sends signals to the brain. This therapy is used along with pharmacotherapy and ECT. Adverse effects of VNS include alterations in patients’ voice, coughing, pharyngitis, sore throat, hoarseness, headache, nausea, vomiting, dyspnea, and paresthesia.

Transcranial magnetic stimulation is a noninvasive and well-tolerated procedure that is FDA approved for use after one failed trial of an antidepressant. Physical exercise may reduce depressive symptoms, but well-controlled studies are needed to verify this.

**Pharmacologic Therapy**

Individual antidepressants, even those within the same class, have important pharmacologic differences ([Tables 38–2 and 38–3]). Monoamine oxidase inhibitors (MAOIs) inhibit the enzyme responsible for the breakdown of 5-HT, NE, and DA. There are two main forms of MAO: While both MAO-A and MAO-B have receptors in the gut, MAO-A has more receptors in the brain, and MAO-B is primarily found in the brain. Inhibition of MAO-A impacts the breakdown of 5-HT, dopamine, epinephrine, and NE. MAO-B is primarily involved in the inhibition of DA and phenethylamine. Dietary restrictions are necessary for MAO-A inhibitors, but not usually for MAO-B inhibitors. The tricyclic antidepressants (TCAs) possess both serotonin reuptake inhibition (SRI) and norepinephrine reuptake inhibition (NRI) properties, but they also block other receptors, including α₁-adrenergic, histamine-1, and muscarinic cholinergic receptors, which contribute to side effects, not efficacy. The primary action of the specific serotonin reuptake inhibitors (SSRIs) is SRI. Bupropion is a NE and DA reuptake inhibitor (NDRI). Venlafaxine, desvenlafaxine, and duloxetine are 5-HT and NE...

Data from Refs. 8 and 10.
reuptake inhibitors (SNRIs) and weak inhibitors of DA reuptake. Compared with venlafaxine and desvenlafaxine, which have primarily SRI activity, duloxetine has more balanced SRI and NRI activities and has a higher affinity for reuptake sites. Nefazodone and trazodone are 5-HT antagonists. Their SRI activity is not as pronounced as that of the SSRIs, but they potently block 5-HT1A receptors, which allow more 5-HT to interact at postsynaptic 5-HT1A sites. In addition, trazodone blocks histaminergic and α-adrenergic receptors, and nefazodone possesses weak NRI and α-adrenergic blocking properties. Vilazodone, a combination of an SRI and a partial agonist at 5-HT1A receptors, is thought to reduce negative feedback on endogenous serotonin receptors which may improve the medications antidepressant effect. Vortioxetine is an agonist/antagonist/partial agonist at various 5-HT receptors. Vortioxetine has affinity for β-adrenergic receptors which may be associated with side effects and histaminic and acetylcholinergic receptors which may have an effect on memory. Finally, mirtazapine is a noradrenergic and specific serotonergic antidepressant. It blocks presynaptic α1 autoreceptors on noradrenergic neurons and heteroreceptors on serotonergic neurons, resulting in increases in NE and 5-HT synaptic concentrations. Mirtazapine also blocks postsynaptic serotonergic receptors and histamine-1 receptors.

### Complementary and Alternative Treatments

St. John’s wort (hypericum perforatum) is an herbal medication that has shown efficacy in mild to moderate depression, but minimal efficacy for moderate to severe depression. It has mild MAO-inhibiting properties. Many patients believe that herbal medications are devoid of adverse effects and drug interactions; however, St. John’s wort can cause gastrointestinal (GI) irritation, headache, fatigue, and nervousness, and it triggers drug interactions through induction of CYP3A4 enzymes, and potentially other mechanisms. The safety and efficacy of St. John’s wort combined with standard antidepressant medications remains unknown.

S-adenosyl methionine (SAM-e), a naturally occurring compound in the body, tends to be lower in people with major depression. Treatment with SAM-e increases blood levels of both S-adenosyl methionine and hydroxyindolactic acid. It is sold as a nutritional supplement and lacks the standardization of medications that are FDA approved.

Low folate levels are associated with a greater risk of depression or a lack of response to antidepressants. Because folic acid prevents neural tube defects in pregnancy and causes few to no adverse effects, it can be used in doses of 0.4 to 1 mg/day to improve the efficacy of the antidepressants.

Low doses of omega-3 fatty acids (eicosapentaenoic, docosahexaenoic acid, or both) have been used adjunctively for major depression. More study is needed to establish their role.

### Adverse Effects

The adverse effects of the antidepressants are often a function of their underlying pharmacologic profiles (see Table 38–3). The TCAs cause sedative, anticholinergic, and cardiovascular adverse effects. Although common, they can also be serious in some cases. The tertiary amines (eg, amitriptyline, imipramine) are more sedative and anticholinergic than the secondary amines (eg, desipramine, nortriptyline). The TCAs have a quinidine-like effect on the heart, which makes them toxic in overdose. The average lethal dose in a young adult is 30 mg/kg, which is typically less than a 1-month supply.

The adverse effect profile of the SSRIs includes sexual dysfunction (eg, delayed or absent orgasms), CNS stimulation (eg, nervousness and insomnia), and GI disturbances (eg, nausea and diarrhea). Sexual dysfunction, common and challenging to manage, often leads to noncompliance. Various strategies to deal with antidepressant induced sexual function include waiting for symptoms to subside, reducing the dosage, permitting periodic “drug holidays,” prescribing adjunctive therapy, and switching antidepressants. However, waiting for symptoms to subside usually does not work, because sexual dysfunction may very well persist throughout the duration of therapy. Reducing the dose and using drug holidays may weaken the antidepressant effects. Thus, clinicians often prescribe adjunctive therapy such as dopaminergic drugs (eg, bupropion, amantadine), 5-HT, antagonists (cyproheptadine, nefazodone), and phosphodiesterase inhibitors (eg, sildenafil) or simply switch to antidepressants with less likelihood of causing these effects, such as bupropion, mirtazapine, or nefazodone.

Bupropion causes insomnia, nightmares, decreased appetite, anxiety, and tremors, but the most concerning adverse effect is seizures. Because of the risk for seizures, patients with a CNS lesion, history of seizures, head trauma, or bulimia should not receive the drug. The daily dose of bupropion should not exceed 450 mg/day (immediate release and extended release), and any single dose of the immediate-release formulation should not exceed 150 mg. The maximum dose of sustained release is 200 mg twice daily. Insomnia and/or nightmares often respond to moving the last daily dose from bedtime to late afternoon.

The adverse effects of the SNRIs are similar to those of the SSRIs. Nausea can be troublesome with venlafaxine and desvenlafaxine, which sometimes necessitates using lower starting doses and giving the medication with food. A dose-related elevation in blood pressure can occur at higher doses, and blood pressure monitoring should be conducted for patients receiving venlafaxine or desvenlafaxine. Duloxetine should not be prescribed to patients with moderate to heavy alcohol use or evidence of chronic liver disease owing to the potential for hepatic injury.

Trazodone causes sedation, and it is used more often as an adjunct with other antidepressants for sleep than as an antidepressant. Priapism is a rare but serious adverse effect in men taking trazodone. It is less likely with nefazodone because it has a weaker effect at α-adrenergic receptors and a balancing of adrenergic effects owing to weak NRI activity. Unfortunately, nefazodone has been associated with development of fatal hepatotoxicity, which has led to a black-box warning and significant reduction in its use. It has been discontinued in some countries.

Mirtazapine can cause sedation and weight gain by blocking histamine-1 receptors. Despite being partially a serotonergic drug, it rarely causes serotonergic-related adverse effects because it also blocks the various postsynaptic 5-HT receptors. Although it carries a bolded warning for neutropenia owing to a handful of cases reported during clinical trials, it is questionable whether neutropenia is more problematic with mirtazapine than other antidepressants.

The relative incidence of adverse effects among the newer antidepressants is shown in Table 38–4.

### Pharmacokinetic Parameters

Pharmacokinetic parameters of the newer antidepressants are shown in Table 38–5. Several antidepressants are not highly protein bound, the most notable of these are venlafaxine and desvenlafaxine. The elimination half-lives of nefazodone and venlafaxine are relatively short compared with the other agents.
Conversely, fluoxetine has a very long half-life (ie, 5–9 days) with chronic dosing, and its active metabolite (norfluoxetine) has an even longer half-life. Because of this, a 5-week washout of fluoxetine is required before starting an MAOI. A 2-week washout is generally considered sufficient for other SSRIs. Sertraline and citalopram also have active metabolites, but these metabolites (desmethylsertraline and desmethylcitalopram, respectively) are only about one-eighth as potent as the parent compounds for SRI activity.31,32,33

**Drug Interactions**

Antidepressant drug interactions can be pharmacokinetic or pharmacodynamic. The usual pharmacodynamic drug interactions involve the “dirty receptors” blocked by some antidepressants. TCAs can cause significant additive effects with other drugs that cause sedation, hypotension, or anticholinergic effects. Similarly, trazodone and mirtazapine can interact with other drugs that cause hypotensive and sedative effects. By far, the most concerning pharmacodynamic interactions are hypertensive crisis and serotonin syndrome, which are both life-threatening. Hypertensive crisis is characterized by sharply elevated blood pressure, occipital headache, stiff or sore neck, nausea, vomiting, and sweating. It may result during MAOI therapy if the patient takes a sympathomimetic drug, such as ephedrine, pseudoephedrine, phenylephrine, phenylpropanolamine, or stimulants such as amphetamines or methylphenidate or if the patient consumes

Data from Refs. 8 and 10.
foods rich in tyramine, such as tap beers, aged cheeses, fava beans, yeast extracts, liver, dry sausage, sauerkraut, or tofu. There are extensive lists of foods and drinks that are not permitted during therapy with MAOIs, and these should always be provided to patients. Because many over-the-counter (OTC) products contain sympathomimetics, patients should always be told to consult with their pharmacist or other clinician before using these drugs. Serotonin syndrome is characterized by confusion, restlessness, fever, abnormal muscle movements, hyperreflexia, sweating, diarrhea, and shivering. It may result when a serotonergic agent is added to any other serotonergic agent, but the MAOIs are strongly associated with severe cases of serotonin syndrome. Serotonin syndrome is complicated by (a) an unawareness by clinicians of the diagnosis and (b) the fact that many implicated drugs are not serotonergic in nature, such as dextromethorphan, meperidine, tramadol, linezolid, triptans, and methylene blue.

Many antidepressants inhibit cytochrome P450 isoenzymes, elevating plasma levels of substrates for those isoenzymes and potentially leading to adverse effects or toxicity (see Table 38–5).

**Dosing**

Antidepressant dosing is summarized in Table 38–6. The extended release formulation of venlafaxine and bupropion allow for once daily dosing. The delayed-release capsule of fluoxetine can be given weekly, which can be started 7 days after the last regular-release capsule or tablet. Selegiline is available as a transdermal patch, and a dose of 6 mg/24 hours can be used without the usual dietary restrictions associated with MAOI use, although patients on the higher doses (9 and 12 mg/24 hours) should follow usual dietary restrictions. Liquid dosage forms and disintegrating tablets of various antidepressants are ideal for patients who have difficulty swallowing tablets or capsules and those who may attempt to “cheek” their medication.

The starting dose is the usual therapeutic dose for most SSRIs, desvenlafaxine, duloxetine, and mirtazapine, but there is usually a need for at least some upward titration of venlafaxine, vilazodone, vortioxetine, bupropion, and nefazodone. An advantage of TCAs is that plasma levels may be used to help guide dosing, especially for those that have well-defined therapeutic plasma level ranges, including nortriptyline (50–150 ng/mL [mcg/L; 190–570 nmol/L]), desipramine (100–160 ng/mL [mcg/L; 375–601 nmol/L]), amitriptyline (75–175 ng/mL [mcg/L; 270–631 nmol/L]), and imipramine (200–300 ng/mL [mcg/L; 713–1070 nmol/L]).

**Efficacy of Pharmacotherapy**

Each antidepressant has a response rate of approximately 60% to 80%, and no antidepressant medication or class has been reliably shown to be more efficacious than another. MAOIs may be the most effective medication for atypical depression, but MAOI use continues to wane because of adverse effects, dietary and drug restrictions, and the possibility of fatal drug interactions. There is some evidence that dual-action antidepressants, such as TCAs and SNRIs, may be more effective in patients with severe depression than the single action drugs such as the SSRIs, but the more general assertion that multiple mechanisms of action confer efficacy advantages is controversial.

**Selection of Medication**

Figure 38–1 depicts a well-known algorithm for the treatment of nonpsychotic MDD—the Texas Medication Algorithm Project (TMAP). Notable aspects of this algorithm include the preferential use of newer antidepressants in the earlier stages of treatment and sequential trials of antidepressant monotherapy prior to the use of combination therapy (see Managing Partial Response or Nonresponse.) Patients undergoing treatment guided by this algorithm fared better than those who received treatment not guided by the algorithm over a 1-year period. Antipsychotics should be combined with antidepressants in cases of depression with psychotic features.

Various factors must be taken into account when selecting antidepressant therapy for a particular patient. The most reliable predictor of response is the patient’s history of response (eg, efficacy, side effects, and overall satisfaction) to antidepressants. To a lesser extent, the history of a first-degree relative’s response to antidepressants may be used to predict a patient’s response. Adverse effect profiles should be considered, because compliance is influenced by tolerability. The patient is the best source of information regarding acceptability of adverse effects. Patients should be educated about how to deal with side effects (eg, using chewing gum, hard candy, or ice chips for dry mouth). The clinician must anticipate and be vigilant for potential drug–drug interactions and drug-disease interactions. For instance, a patient with a seizure disorder would be an inappropriate candidate for bupropion therapy. The presence of comorbid psychiatric conditions can suggest the best antidepressant to choose. For example, an SSRI can treat both MDD and panic disorder, obviating the need for two separate medications. Fluvoxamine, an SSRI, is marketed for obsessive compulsive disorder, although it also treats depression. The potential for accidental or intentional overdose and affordability of the medication also influence drug selection.

**Time Course of Response**

Antidepressants do not produce an immediate clinical response. Improvement in physical symptoms such as sleep, appetite, and energy, can occur within the first or second week of treatment. Although a meta-analysis suggests earlier effects of antidepressant treatment, it is widely accepted that approximately 2 to 4 weeks of treatment is required before improvement is seen in emotional symptoms such as sadness and anhedonia. As long as 6 to 8 weeks may be required to see full antidepressant effects.

**Managing Partial or No Response**

Approximately one-third of patients with MDD do not respond satisfactorily to their first antidepressant medication. In such cases, the clinician must evaluate the adequacy of antidepressant therapy, including dosage, duration, patient compliance, verification of the patient’s diagnosis, and reconsideration of clinical factors that could be impeding successful therapy, such as concurrent medical conditions (eg, thyroid disorder), comorbid psychiatric conditions (eg, alcohol abuse), and psychosocial issues (eg, marital stress).

A series of reports from the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial revealed that remission is associated with a better overall prognosis than improvement alone. STAR*D also established that in patients with a greater level of nonresponse to treatment, clinicians are less likely to push the patient to achieve remission, and in addition, those patients with the greatest levels of nonresponse had the highest rates of relapse. STAR*D established some successful treatment recommendations. For patients experiencing a partial response, extending the medication trial and/

⁴Brand no longer available in the United States.
⁵Maximum dose is 40 mg/day.
⁶Upper limit of this range is the maximum dose.

ALT, alanine aminotransferase; AST, aspartate aminotransferase; MAOI, CI Cr, creatinine clearance; monoamine oxidase inhibitor; NaSSA, noradrenergic and specific serotonergic antidepressant; NDRI, norepinephrine and dopamine reuptake inhibitor; SARI, serotonin antagonist and reuptake inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; SRI/5-HT₁₅ partial agonist-serotonin reuptake inhibitor/serotonin₅₂A partial agonist; TCA, tricyclic antidepressant.

Data from Refs. 12, 19, 21, 33, and 39.

or using higher doses within the recommended dosage range may be helpful. Another option is augmentation therapy, ie, adding another medication that generally is not used as an antidepressant, such as, lithium, buspirone, or triiodothyronine.⁴⁰ Second-generation antipsychotics, aripiprazole, and the extended-release formulation of quetiapine, are approved by the FDA for augmenting partial response to antidepressants.⁴¹ Whereas efficacy has been suggested for dopaminergic drugs (eg, pramipexole) and psychostimulants (eg, methylphenidate), various other medications such as anticonvulsants (eg, valproic acid), modafinil, and estrogen have anecdotal evidence supporting their use as augmenting agents. A third option is combination therapy, whereby another antidepressant, typically from a different pharmacologic class is added to the first
FIGURE 38–1. Strategies for the treatment of nonpsychotic major depression. Redrawn with permission from the Texas Medication Algorithm Project.35
antidepressant.42 Examples include combining bupropion and SSRIs or combining TCAs and SSRIs.

Switching to a different antidepressant is a common strategy for patients who have had no response to initial antidepressant therapy, but also is acceptable in cases of partial response. Relative to augmentation or combination therapy, advantages of switching include improved compliance, decreased costs, and less concern over drug–drug interactions. Disadvantages include loss of time, and loss of any improvement seen with the initial drug.45 When switching from one antidepressant to another, clinicians may choose to stay within the same class (eg, sertraline to fluoxetine) or go outside of the class (eg, paroxetine to venlafaxine). The olanzapine–fluoxetine combination medication Symbyax has been approved for treatment–resistant depression.43

Nonpharmacologic interventions in cases of treatment nonresponse include adding or changing to psychotherapy or initiating ECT.

**Duration of Therapy**

Treatment of MDD encompasses three phases: acute, continuation, and maintenance (Figure 38–2)46 The goal of antidepressant therapy is remission of MDE symptoms. This acute phase of treatment typically lasts 6 to 12 weeks. **KEY CONCEPT** Because the typical MDE lasts 6 months or longer, if antidepressant therapy is interrupted after the acute phase, the patient may relapse into a depressive episode. When treating the first depressive episode, antidepressants must be given for an additional 4 to 9 months in the continuation phase to prevent relapse.

Maintenance treatment takes place after the normal course of a MDE to prevent recurrence, which is the development of future episodes. This phase can last for years, or for a lifetime. Although patients who have a MDE should receive acute and continuation treatment, not all of them require maintenance treatment, because not all patients experience multiple major depressive episodes. In some patients with multiple episodes, many years may separate the episodes. Therefore, the clinician must consider various factors in determining whether an individual requires maintenance treatment. A major factor is the number of prior episodes experienced by the patient. The more prior episodes experienced, the higher the risk for future episodes. After three or more MDEs, patients are generally given lifelong maintenance treatment because of the high (ie, 90%) chance of experiencing additional episodes. Other factors to consider are the severity of previous episodes, if suicide attempts were made, whether psychotic features were present, and patient preference. The dose of the antidepressant required in the acute phase of treatment should be sustained during the continuation and maintenance phases.

**Discontinuation of Therapy**

When discontinuing therapy, it is best to gradually taper the antidepressant for two reasons. First, almost all antidepressants can produce withdrawal syndromes if discontinued abruptly or tapered too rapidly, especially antidepressants with shorter half-lives (eg, venlafaxine, paroxetine, and fluvoxamine).37 Withdrawal syndromes can cause sleep disturbances, anxiety, fatigue, mood changes, malaise, GI disturbances, and a host of other symptoms which often are confused with depressive relapse or recurrence.57 In general, a tapering schedule involving a small dosage decrement (eg, paroxetine 5 mg) every 3 to 5 days should prevent significant withdrawal symptoms.56 Second, depressive symptoms may return on taper or discontinuation of the antidepressant. So, if the medication is gradually tapered, then early signs of depression can be countered with a return to the original dosage and a potentially quicker response.57 Depending on the patient’s illness and the clinical circumstances, tapering of the antidepressant can be extended for weeks or even months because of the concern over relapse or recurrence.

**Special Considerations**

**Pregnant or Breastfeeding Patients**

Depression is quite common in pregnancy, especially for women with a history of recurrent depression. Both maternal and fetal well-being must be considered when weighing risks and benefits of antidepressant therapy during pregnancy. While somewhat controversial, the prescribing information for paroxetine was changed to reflect findings of an increased risk of congenital malformations, particularly atrial and ventricular septal defects, in infants born to women taking the drug during the first trimester. Sertraline and citalopram have also been associated with septal heart defects when taken during the first trimester. In addition, the incidence of having a baby with a septal heart defect was four times higher for mothers taking more than one SSRI in the first trimester. More recent studies have questioned these results.43

---

**FIGURE 38–2.** The course of depression and phases of treatment. Data from Refs. 10 and 19.
Antidepressants are reported to occasionally cause perinatal sequelae, such as poor neonatal adaptation, respiratory distress, feeding problems, and jitteriness. Data on the long-term effects of in utero antidepressant exposure are limited. Sertraline, fluoxetine, citalopram, and the TCAs have the greatest reproductive safety data and should be considered first-line treatments when pharmacotherapy is indicated. There is some drug exposure to the infant from nursing mothers who are taking antidepressants. Although there have been rare anecdotal reports of adverse effects (ie, respiratory depression and seizure-like episodes) in infants exposed to antidepressants through breast milk, no rigorous study has confirmed this, and it is generally accepted that the benefits of breastfeeding outweigh the risks to the infant posed by antidepressant exposure. However, the decision needs to be made on an individual basis.

**Geriatric Patients**

Depression in older adults is under recognized and undertreated. Although not uncommon in community samples, MDD is prevalent among those living in long-term care facilities. Barriers to recognition of geriatric depression include “masked” presentations, that is complaints of physical symptoms (eg, pain and GI problems) instead of mood symptoms, the frequent presence of medical illnesses, and the overlap of mood and cognitive symptoms with those of dementia. Age-related pharmacokinetic and pharmacodynamics changes cause geriatric patients to be more sensitive to antidepressant medications. Thus, lower starting doses of antidepressants and slow upward titrations as tolerated are recommended for geriatric patients. The SSRIs are chosen frequently for geriatric depression because of their overall favorable adverse effect profiles and low toxicity; most TCAs are avoided due to problematic anticholinergic, cardiovascular, and sedative properties. The TCAs desipramine and nortriptyline are more tolerable in terms of these adverse effects and may be used in geriatric depression. Other newer antidepressants, such as bupropion, venlafaxine, nefazodone, and mirtazapine, are alternatives for the treatment of geriatric patients.

**Pediatric Patients**

Antidepressant medications appear to be useful for certain children and adolescents, particularly those who have severe or psychotic depression, fail psychotherapy, or experience chronic or recurrent depression. Fluoxetine and escitalopram are the only antidepressants FDA approved for depression in children younger than 18 years. The SSRIs generally are considered the initial antidepressants of choice, but comorbid conditions may favor alternative agents. "Behavioral activation" can occur with the SSRIs, including such symptoms as impulsivity, silliness, daring conduct, and agitation. Desipramine must be used with caution in this population because of several reports of sudden death, and baseline and follow-up electrocardiography is warranted when using desipramine in pediatric patients.

The FDA warns that antidepressants increase the risk of suicidality (ie, suicidal thinking and behavior) in children and young adults. A large analysis of clinical trials showed the risk of such events was 4% for antidepressants versus 2% for placebo, although no completed suicides occurred in the trials. Because antidepressants carry a black-box warning regarding suicidality, medication guides must be distributed with each prescription or refill of antidepressants. Pediatric patients and young adults should be observed closely for suicidality, worsened depression, agitation, irritability, and unusual changes in behavior, especially during the initial few months of therapy and at times of dosage changes. Furthermore, families and caregivers should be advised to monitor patients for such symptoms.

**Suicidal Patients**

The FDA has determined that in addition to children and adolescents, there is an increased risk of suicidality in patients between the ages of 18 and 24 years. Similar monitoring for suicidality and clinical worsening that is mandated for pediatric patients should also be followed for these young adult patients. Whereas the TCAs and MAOIs have narrow therapeutic indices, the SSRIs, SNRIs, nefazodone, and mirtazapine have wide therapeutic indices.

**Patient Counseling**

Major counseling points are outlined in Table 38–7. Lack of patient understanding concerning optimal antidepressant therapy frequently leads to partial or noncompliance with therapy, thus the primary purpose of antidepressant counseling is to enhance compliance and improve outcomes.

**OUTCOME EVALUATION**

**Symptom Assessment**

The patient interview should assess response of target symptoms. Rating scales are useful in this regard. The Hamilton Depression Scale (HAM-D) is a 17-item, clinician administered scale where less than 6 corresponds with normal mood, and greater than 25 is associated with severe depression. The Beck Depression Inventory (BDI) is a patient-rated scale where 9 or less is associated with normal mood, and 20 to 29 corresponds to moderate to severe depression. The Patient Health Questionnaire (PHQ-9) is a 9-item scale which rates 4 or less as normal mood and greater than 20 as severe depression.

**Patient Education**

Patients should be educated that while they may see some improvement in some symptoms like sleep and appetite as early as the first week, generally at least 4 to 8 weeks is required for optimal mood changes to occur. Patients should also recognize common side effects including, how long those side effects might last, and if there are any simple remedies for treatment (eg, using ice chips or sugarless gum for a dry mouth).
Monitoring Adverse Effects

Evaluation for suicidal ideation should be a part of every patient visit. Patients can be taught to manage side effects such as sedation, constipation, and dry mouth. Potential side effects such as weight gain and sexual dysfunction should be discussed with the patient and monitored at each visit. Venlafaxine may increase blood pressure, and patients should have their blood pressure checked at each visit. Patients with cardiovascular risk factors or over the age of 40 should have an electrocardiogram (ECG) completed prior to initiating a TCA. Patients taking TCAs such as amitriptyline, imipramine, nortriptyline, or desipramine should have antidepressant serum levels checked if overdose, side effects, or nonadherence is an issue. Patients should be monitored for serotonin syndrome if they are taking two or more serotonergic medications.

### Patient Care Process

#### Patient Assessment:
- Determine if the patient is experiencing symptoms of depression.
- Review the medical history. Does the patient have any medical problems that might cause the current symptoms?
- Conduct a medication history (including prescriptions, OTC medications, and dietary supplements) to identify possible causes of depression.
- Review available laboratory tests, especially thyroid function tests, renal and hepatic function.

#### Therapy Evaluation:
- Determine if antidepressant therapy is needed.
- Evaluate past history of depression treatment, including response and adverse effects.
- Assess efficacy, safety, and adherence to current pharmacotherapy.

- Ensure that the patient can afford and access prescribed medications.

#### Care Plan Development:
- Choose lifestyle modifications and antidepressant therapy that are safe and effective.
- Determine if the drug dosage is optimal for treatment. Take an algorithmic approach to treatment (see Figure 38–1).
- Address patient concerns.
- Discuss with the patient the importance of medication adherence and lifestyle modifications.

#### Follow-up Evaluation:
- Follow-up to assess effectiveness and safety of therapy.
- Monitor the patient every 3 to 6 months to assess for return of symptoms. Determine if patient is experiencing any adverse effects or drug interactions.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying bipolar disorder.
2. Recognize the symptoms of a manic episode and depressive episode in patients with bipolar disorder.
3. Identify common comorbidities of bipolar disorder.
4. Recognize the Diagnostic and Statistical Manual of Mental Disorders, 5th edition, criteria for bipolar disorder as well as the subtypes of bipolar I disorder, bipolar II disorder, and cyclothymic disorder.
5. List the desired therapeutic outcomes for patients with bipolar disorder.
6. Explain the use of drugs as first-line therapy in bipolar disorder, including appropriate dosing, expected therapeutic effects, potential adverse effects, and important drug–drug interactions.
7. Recommend individualized drug therapy for acute treatment and relapse prevention based on patient-specific data.
9. Recommend treatment approaches for special populations of patients with bipolar disorder, including pediatric patients, geriatric patients, and pregnant patients.
10. Educate patients with bipolar disorder about their illness, drug therapy required for effective treatment, and the importance of adherence.

INTRODUCTION

Bipolar disorder is characterized by one or more episodes of mania or hypomania, often with a history of one or more major depressive episodes. It is chronic, with relapses and remissions. Mood episodes can be manic, depressed, or mixed. They can be separated by periods of long stability or cycle rapidly. They occur with or without psychosis. Disability and other consequences (eg, increased risk of suicide) can be devastating to patients and families. Correct and early diagnosis and treatment are essential to prevent complications and maximize response to treatment.

Epidemiology and Etiology

Epidemiology

Bipolar disorders are categorized into bipolar I disorder, bipolar II disorder, and other specified and unspecified bipolar and related disorders. Bipolar I disorder is characterized by one or more manic or mixed mood episodes. Bipolar II disorder is characterized by one or more major depressive episodes and at least one hypomanic episode. Hypomania is an abnormally and persistently elevated, expansive, or irritable mood but not of sufficient severity to cause significant impairment and does not require hospitalization. The lifetime prevalence of bipolar I disorder is estimated at 0.6%. The lifetime prevalence of bipolar II disorder is about 0.4%. When including the entire spectrum of bipolar disorders, the prevalence is approximately 3%.

Bipolar I disorder affects men and women equally. Bipolar II is more common in women. Rapid cycling and mixed mood episodes occur more in women. In all, 78% to 85% of individuals with bipolar disorder report having another Diagnostic and Statistical Manual, 5th edition (DSM-5), diagnosis during their lifetime. The most common comorbid conditions are anxiety, substance abuse, and impulse control disorders. Medical comorbidities are common.

The mean age of onset is 20 years, although onset may occur in early childhood to the mid-40s. If onset occurs after age 60, it is probably due to medical causes. An early onset is associated with greater comorbidities, more mood episodes, a greater proportion of days depressed, and greater lifetime risk of suicide attempts compared with later onset. Substance abuse and anxiety disorders are more common in patients with early onset. Patients with bipolar disorder have higher rates of suicidal thoughts, attempts, and completed suicides than the general population.

Etiology

The precise etiology is unknown. Thought to be genetically based, bipolar disorder is influenced by a variety of factors that may enhance gene expression. These include trauma, environmental factors, anatomical abnormalities, and exposure to chemicals or drugs.
PATHOPHYSIOLOGY

Neurochemical

The pathophysiology remains incompletely understood. Imaging techniques such as positron emission tomography (PET) scans and functional magnetic resonance imaging (fMRI) are used to elucidate the cause. Historically, research focused on neurotransmitters such as norepinephrine (NE), dopamine (DA), and serotonin. One hypothesis is that bipolar disorder is caused by an imbalance of cholinergic and catecholaminergic activity. Serotonin is suggested to modulate catecholamines. Dysregulation of this relationship could cause mood disturbance. A variety of neurotransmitters are involved that interact with multiple neurochemical and neuroanatomic pathways. The pathophysiology is also hypothesized from the mechanisms of lithium and other drugs. Lithium, valproate, and carbamazepine all have similar effects on neuronal growth that are reversible by inositol, supporting a hypothesis that bipolar disorder may be related to inositol disturbance. Brain-derived neurotrophic factor (BDNF) may play a role in bipolar disorder. Serum BDNF is low in mania and improves with treatment.

Genetic

Results of family studies suggest a genetic basis. Lifetime risk of bipolar disorder in relatives of a bipolar patient is 40% to 70% for a monozygotic twin and 5% to 10% for other first-degree relatives.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis of Bipolar Disorder

**KEY CONCEPT** Patients presenting with depressive or elevated mood features and a history of abnormal or unusual mood swings should be assessed for bipolar disorder. Bipolar disorder is categorized into four subtypes: bipolar I (periods of major depressive, manic, and/or mixed episodes); bipolar II (periods of major depression and hypomania), cyclothymic disorder (periods of hypomanic episodes and depressive episodes that do not meet all criteria for diagnosis of a major depressive episode), and other specified and unspecified bipolar and related disorders. The defining feature of bipolar disorder is one or more manic or hypomanic episodes in addition to depressive episodes that are not caused by a medical condition, substance abuse, or other psychiatric disorder.

Initial and subsequent episodes are mostly depressive. Studies show bipolar I patients spend about 32% of weeks with depressive symptoms compared with 9% of weeks with manic or hypomanic symptoms. Patients with bipolar II disorder spend 50% of weeks symptomatic for depression and only 1% with hypomania. Because patients may present with depression and spend more time depressed than with mood elevation, bipolar disorder is often misdiagnosed or underdiagnosed. It is helpful to use a screening tool such as the mood disorder questionnaire.

DSM-5 criteria for the diagnosis of bipolar disorder are summarized in Table 39-1.

- **Bipolar I Disorder**

  The diagnosis of bipolar I disorder requires at least one episode of mania for at least 1 week with a persistently elevated, expansive, or irritable mood with related symptoms of decreased need for sleep, excessive energy, racing thoughts, a propensity to be involved in high-risk activities, and excessive talkativeness. Bipolar I depression can be misdiagnosed as major depressive disorder (MDD); therefore, it is essential to rule out past episodes of hypomania or mania. If bipolar depression is mistaken for MDD and the patient is treated with antidepressants, it can precipitate a manic episode or induce rapid cycling.

- **Bipolar II Disorder**

  The distinguishing feature of bipolar II disorder is a current or past hypomanic episode and a current or past major depressive episode. Irritability and anger are common. There cannot have been a prior full-manic episode.

- **Cyclothymic Disorder**

  Cyclothymic disorder is a chronic mood disturbance lasting at least 2 years (1 year in children and adolescents) and characterized

FOI, flight of ideas.

*Impairment in social or occupational functioning; need for hospitalization because of potential self-harm, harm to others, or psychotic symptoms.

The disorder is not caused by a medical condition (eg, hypothyroidism) or substance-induced disorder (eg, antidepressant treatment, medications, electroconvulsive therapy).

Suicide

Differential Diagnosis

- Panic disorder
- Personality disorders
- Anxiety disorders
- Alcohol and substance abuse or dependence

Comorbid Psychiatric and Medical Conditions

- Patients with bipolar disorder have high risk of suicide. Factors that increase risk are early age at onset, high number of depressive episodes, comorbid alcohol abuse, personal history of antidepressant-induced mania, and family history of suicidal behavior. About one-third of individuals with bipolar disorder report a previous attempt. One of five attempts is fatal, in contrast to one of 10 to one of 20 in the general population.

- Personality disorders are inflexible and maladaptive patterns of behavior that deviate markedly from expectations of society beginning in adolescence or early adulthood. Personality disorders and bipolar disorder may be comorbid, and patients with personality disorders may have mood symptoms. The two diagnoses are distinguished by the predominance of mood symptoms and the episodic course of bipolar disorder in contrast to the stability and persistence of the behavioral patterns of personality disorders.

- Schizophrenia and bipolar disorder share certain symptoms, including psychosis in some patients. The prominence of mood symptoms and the history of mood episodes distinguish bipolar disorder and schizophrenia. In addition, psychosis of schizophrenia occurs in the absence of prominent mood symptoms. Schizoaffective disorder may also be considered when developing a differential diagnosis. Schizoaffective disorder is characterized by a period of illness during which there is a major depressive episode or a manic episode, concurrent with symptoms that meet criterion A for schizophrenia (eg, delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and/or negative symptoms such as affective flattening, alogia, or avolition). During the same period of illness, there have been delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms. Personality disorders are inflexible and maladaptive patterns of behavior that deviate markedly from expectations of society beginning in adolescence or early adulthood. Personality disorders and bipolar disorder may be comorbid, and patients with personality disorders may have mood symptoms. The two diagnoses are distinguished by the predominance of mood symptoms and the episodic course of bipolar disorder in contrast to the stability and persistence of the behavioral patterns of personality disorders.

- Comorbid Psychiatric and Medical Conditions

Lifetime prevalence rates of comorbidity with bipolar disorder are as high as 58%. Comorbidities, especially substance abuse, make establishing a diagnosis more difficult and complicate treatment. Comorbidities also place the patient at risk for a poorer outcome, high rates of suicidality, onset of depression, and higher costs of treatment. Psychiatric comorbidities include:

  - Personality disorders
  - Alcohol and substance abuse or dependence
  - Anxiety disorders
  - Panic disorder

Patient Encounter, Part 2: Medical History, Physical Exam, Laboratory Exam

Your interview reveals the following information:

**PMH:** No known medical problems except a history of hypertension marginally controlled by hydrochlorothiazide 50 mg/day. Joan also admits to being treated for chlamydia last year.

**PPH:** Noncontributory

**FH:** Parents alive and well. The patient’s maternal grandmother was hospitalized several times at the state psychiatric hospital for treatment of unspecified mental illness in the remote past. A maternal aunt committed suicide 5 years ago. The patient’s father is a recovering alcoholic who regularly attends AA. The patient has one brother and sister in good health.

**SH:** Joan admits to numerous sexual partners beginning at the age of 18 when she first went away to college. She states none of her relationships has lasted more than a few weeks, although she would like to eventually get married. She is presently majoring in mathematics and previously aspired to be a high school teacher; however, she has failing grades in most of her classes this semester. Her roommates have complained about her coming in late at night and have also complained about Joan’s use of drugs in their apartment. Joan admits to partying several nights each week as well as more on weekends.

**SUH:** The patient denies use of tobacco products, hallucinogens, amphetamines, opioids, benzodiazepines, or intravenous drugs. She does admit to smoking marijuana on a daily basis, has experimented with cocaine in the past, and drinks heavily on the weekends. She does not drink coffee but consumes several cans of caffeinated soda each day. She denies use of vitamins or herbal supplements.

**Meds:** Hydrochlorothiazide 50 mg by mouth daily

**ROS:** Decreased appetite with recent 8 lb (3.6 kg) weight loss, decreased need for sleep, increased energy, distractibility, pressured speech, hypersexuality. LMP 2 weeks ago.

**PE:**

**VS:** BP 150/90, P 94, RR 18, T 98.7°F (37.1°C)

**HEENT:** PERRLA. Extraocular movements intact. Nares patent. Ear canals patent and eardrums easily visualized. Neck supple without JVD, bruits, or lymphadenopathy. Thyroid smooth, symmetric and nontender.

**CV:** Heart with regular rate and rhythm; no murmurs, gallops, or rubs.

**Abdomen:** Soft, nontender, without organomegaly or masses. Positive bowel sounds in all four quadrants.

**Exts:** Without clubbing, cyanosis, or edema. Peripheral pulses full and equal bilaterally.

**CN:** II-XII intact.

**Labs:** Urine drugs screen + for THC; HIV negative; serum β-HCG negative.

Considering this additional information, what is the most likely diagnosis?
Patients presenting with depressive or elevated mood features and a history of abnormal or unusual mood swings should be assessed for bipolar disorder.

**General**
The patient may present in a hypomanic, manic, depressed, or mixed state and may or may not be in acute distress.

**Symptoms**
*Mood and Affect:*
- Mood elevation
- Expansive mood
- Irritable mood
- Depression
- Hopelessness
- Suicidality

*Physical and Behavioral:*
- Agitation
- Impulsivity
- Aggression
- Rapid, pressured speech
- Insomnia (sometimes for days or weeks)
- Hypersexuality
- Increased physical energy
- Inflated self-esteem, boasting, grandiosity
- Heightened interest in pleasurable activities with a high risk of negative consequences (eg, spending sprees, promiscuity)
- Fatigue
- Hypersomnia

**Thought Processes, Content, and Perceptions:**
- Racing thoughts, FOI, distractibility
- Delusions of grandeur, ideas of reference, persecution, wealth, religion

**Psychosocial**
- Substance use
- Disrupted relationships
- Job loss

**Laboratory and Other Diagnostic Assessments**
*KEY CONCEPT* The diagnosis of bipolar disorder is made based on clinical presentation, a careful diagnostic interview, and a review of the history. There are no laboratory examinations, brain imaging studies, or other procedures that confirm the diagnosis, but such testing can be done to rule out other medical diagnoses.

- Urinalysis with culture, urine drug toxicology, thyroid function, and complete blood count in elderly patients to rule out infection and anemia
- Mood disorder questionnaire, completed by the patient, asks about common symptoms of bipolar disorder, problems caused by the symptoms, and family history in a "yes" or "no" answer format. It is then scored by the clinician

Suicidality risk is increased in the presence of:
- Substance abuse
- Prior suicide attempts and lethality of attempts
- Access to a means of suicide
- Command hallucinations or psychosis
- Severe anxiety
- Family history of attempted or completed suicide

**Medical comorbidities include:**
- Migraine
- Multiple sclerosis
- Cushing syndrome
- Brain tumor
- Head trauma

**TREATMENT**

**Desired Outcomes**
*KEY CONCEPT* Goals of treatment are to reduce symptoms, induce remission, prevent relapse, improve patient functioning, and minimize adverse effects of drug therapy.

**General Approach to Treatment**
Treatment guidelines for manic and depressive episodes of bipolar disorder are included in Table 39–2.
### Table 39–2

**Guidelines for the Acute Treatment of Mood Episodes in Patients with Bipolar I Disorder**

#### Acute Manic or Mixed Episode

- **General guidelines**
  - Assess for secondary causes of mania or mixed states (e.g., alcohol or drug use)
  - Treat substance abuse
- **Treat substance abuse**
  - Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy
- **Alternative medication treatment options:**
  - Carbamazepine; if patient does not respond or tolerate, consider atypical antipsychotic (e.g., olanzapine, quetiapine, risperidone) or oxcarbazepine
- **Second, if response is inadequate, consider a two-drug combination:**
  - Lithium or valproate or carbamazepine
  - Anticonvulsant or an atypical antipsychotic
  - Anticonvulsant plus an anticonvulsant or atypical antipsychotic

#### Acute Depressive Episode

- **General guidelines**
  - Assess for secondary causes of depression (e.g., alcohol or drug use)
  - Taper off antidepressants, stimulants, and caffeine if possible
- **Treat substance abuse**
  - Encourage good nutrition (with regular protein and essential fatty acid intake), exercise, adequate sleep, stress reduction, and psychosocial therapy

#### Hypomania

- First, optimize current mood stabilizer or initiate mood-stabilizing medication: lithium
- Alternative medication treatment options: carbamazepine
- Second, if response is inadequate, consider a two-drug combination:
  - Lithium or valproate or carbamazepine
  - Anticonvulsant or an atypical antipsychotic
  - Anticonvulsant plus an anticonvulsant or atypical antipsychotic

#### Mild to Moderate Depressive Episode

- First, initiate and/or optimize mood-stabilizing medication: lithium
- Alternative anticonvulsants: valproate, carbamazepine, or oxcarbazepine

#### Severe Depressive Episode

- First, two- or three-drug combinations: lithium, valproate, or carbamazepine
- Alternative anticonvulsants: valproate, carbamazepine, or oxcarbazepine

---

ECT, electroconvulsive therapy; MAOI, monoamine oxidase inhibitor; SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

4. Use standard therapeutic serum concentration ranges if clinically indicated; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; valproate is preferred over lithium for mixed episodes and rapid cycling; lithium and/or lamotrigine is preferred over valproate for bipolar depression.

5. Lamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated to decrease adverse effects if used for maintenance therapy of bipolar I disorder. A drug interaction and a severe dermatologic rash can occur when lamotrigine is combined with valproate (ie, lamotrigine doses must be halved from standard dosing titration).

6. Antidepressant monotherapy is not recommended for bipolar depression. Bupropion, SSRIIs (e.g., citalopram, escitalopram, or sertraline), and SNRIs (e.g., venlafaxine) have shown good efficacy and fewer adverse effects in the treatment of unipolar depression; MAOIs and TCAs have more adverse effects (e.g., weight gain) and can have a higher risk of causing antidepressant-induced mania; fluoxetine, fluvoxamine, nefazodone, and paroxetine inhibit liver metabolism and should be used with caution in patients on concomitant medications that require cytochrome P450 clearance; paroxetine and venlafaxine have a higher risk for a discontinuation syndrome.

7. ECT is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, anticonvulsants, lithium, benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

Data from Refs. 14 and 38.

Although it is a goal of treatment, not all patients achieve remission. The mainstay of drug therapy has been mood-stabilizing drugs but research based on multiple treatments indicates antipsychotic drugs, both first-generation (FGAs) and second-generation (SGAs), may be more effective for acute mania. Antipsychotic drugs may be used as monotherapy or adjunctively with mood-stabilizing drugs. A person entering treatment for a first mood episode in bipolar disorder must have a complete assessment and careful diagnosis to rule out nonpsychiatric causes. A variety of conditions can cause similar symptoms (Table 39–3). Because early and accurate diagnosis is essential to maximizing response to treatment, pharmacologic and nonpharmacologic therapy should begin as soon as possible. Treatment is often lifelong. Comorbid conditions should also be addressed.

**Suicidality Risk**

Patients should be assessed for potential for violence and harm to others. Friends or family can be asked to remove the home guns, caustic chemicals, medications, and objects that patients might use to harm themselves or others. Risk factors for suicide include severity of depression, feelings of hopelessness, comorbid personality disorder, and a history of a previous suicide attempt.

**Nonpharmacologic Therapy**

Interpersonal, family, or group psychotherapy with a qualified therapist or clinician assists individuals with bipolar disorder to improve functional outcomes and may help treat or prevent mood episodes, establish a daily routine and sleep schedule, and improve interpersonal relationships.

Cognitive-behavioral therapy (CBT) is a type of psychotherapy that stresses the importance of recognizing patterns of cognition (thought) and how thoughts influence subsequent feelings and behaviors. Other people, situations, and events external to the individual are not seen as the sources of thoughts and behaviors. With CBT, patients are taught self-management skills to change negative thoughts even if external circumstances do not change.

Electroconvulsive therapy (ECT) is the application of electrical impulses to the brain for the treatment of severe depression, mixed states, psychotic depression, and treatment refractory mania. It also may be used in pregnant women who cannot take carbamazepine, lithium, or divalproex.

Education for patients, families, and groups about chronicity of bipolar disorder and self-management through sleep hygiene, nutrition, exercise, stress reduction, and abstinence from alcohol or drugs is critical to success. The development of a crisis intervention plan is essential.

**Pharmacologic Therapy**

The primary treatment modality for manic episodes is mood-stabilizing agents or antipsychotic drugs, often in combination.

- Mood-stabilizing drugs are first-line treatments and include lithium, divalproex, carbamazepine, and lamotrigine. The SGAs, including risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, luradusone, and asenapine, are approved for treatment of acute mania. Lithium, lamotrigine, aripiprazole, olanzapine, and quetiapine are approved for maintenance therapy. Quetiapine’s maintenance therapy indication in bipolar I disorder is adjunctive with lithium or divalproex. Drugs used with less research support and without Food and Drug Administration (FDA) approval include topiramate and oxcarbazepine. Benzodiazepines are used adjunctively for mania.

The primary treatment for depressive episodes in bipolar disorder is mood-stabilizing agents or certain antipsychotics.

Among antipsychotics, quetiapine as monotherapy, luradusone as monotherapy or adjunctive to lithium or divalproex, and olanzapine in combination with fluoxetine are approved. Antidepressants can be used but along with a mood stabilizer to reduce risk of a mood switch to mania and after the patient has failed to respond adequately to mood-stabilizing therapy. Evidence of efficacy of antidepressant drugs in bipolar depression is considered controversial. Combinations of two mood-stabilizing drugs or a mood-stabilizing drug and either an antipsychotic or antidepressant drug are common, especially in acute mood episodes.

The primary treatment for relapse prevention is mood-stabilizing agents, often combined with antipsychotic drugs. Aripiprazole, olanzapine, and quetiapine are approved for maintenance therapy.

Table 39–4 includes a summary of current drug therapy for bipolar disorder. An algorithm for treatment of bipolar mania is shown in Table 39–2.

**Mood-Stabilizing Drugs**

The optimal mood-stabilizing drug is effective in treatment of acute mania and acute bipolar depression and in prevention of manic relapse and bipolar depression relapse. All currently approved mood-stabilizing drugs have demonstrated efficacy over placebo for one or more of these areas, but there are differences among them with regard to specific patient populations. The choice of treatment is dictated by patient characteristics and history. Few studies systematically compare mood stabilizers with each other. Efficacy of individual agents in placebo-controlled trials is similar. Lithium and divalproex are first-choice drugs for the classic presentation of bipolar disorder.

<th>Drug</th>
<th>Trade Name(s)</th>
<th>Formulations</th>
<th>Dosage</th>
<th>Use</th>
</tr>
</thead>
</table>
| Clonazepam            | Klonopin, generic | Tablets: 0.5, 1, 2 mg  
Wafers: 0.125, 0.25, 0.5, 1, 2 mg | 0.5–20 mg/day in divided doses or one  
dose at bedtime | Use in combination with other drugs  
for the acute treatment of mania or  
mixed episodes |
| Clonazepam            |               | Tablets: 0.5, 1, 2 mg  
Oral solution: 2 mg/mL  
Injection: 2, 4 mg/mL | 2–10 mg/day in divided doses or one  
dose at bedtime | |
| Oxcarbazepine         | Trileptal, generic | Tablets: 150, 300, 600 mg  
Suspension: 300 mg/5 mL | 300–1200 mg/day in two divided doses  
Doses should be slowly adjusted up  
and down according to response and  
adverse effects (eg, 150–300 mg twice  
daily and increase by 300–600 mg/day  
at weekly intervals) | May cause fewer adverse drug–drug  
interactions than carbamazepine,  
but causes more gastrointestinal side  
effects and hyponatremia. Evidence  
is limited regarding efficacy |

12/50 mg | 50–800 mg/day in divided doses or once  
daily when stabilized | Used as monotherapy or in combination with lithium or  
divalproex for acute treatment of mania, mixed states for  
bipolar I disorder, and depression of bipolar I and bipolar  
II disorder. Used adjunctively with lithium or divalproex  
for relapse prevention of bipolar mania and depression |
| Quetiapine            | Seroquel  
Seroquel XR | Tablets: 25, 50, 100, 200, 300, 400 mg  
ER tablets: 50, 150, 200, 300, 400 mg | 0.5–6 mg/day in one or two doses | Use as monotherapy or adjunctively with lithium or  
divalproex for acute mania or mixed episodes of bipolar I disorder |
| Risperidone           | Risperdal, generic  
Risperdal M-Tabs  
Risperdal Consta | Tablets: 0.25, 0.5, 1, 2, 3, 4 mg  
Oral solution: 1 mg/mL  
Tablets, orally disintegrating: 0.5, 1,  
2, 3, 4 mg  
Long-acting injectable: 12.5, 25,  
37.5, 50 mg | 0.5–6 mg/day in one or two doses | Use as monotherapy or adjunctively with lithium or  
divalproex for acute mania or mixed episodes of bipolar I disorder |
| Ziprasidone           | Geodon        | Capsules: 20, 40, 60, 80 mg | 40–160 mg/day in divided doses | Use as monotherapy or adjunctively with lithium or  
divalproex for acute mania or mixed episodes of bipolar I disorder |

*DIVALPROEX, divalproex; ER, extended release; FDA, Food and Drug Administration; SR, sustained release; OFC, olanzapine-fluoxetine combination. Data from Refs. 13, 15, 20–22, 24, 27–29, and 38.*
Lithium Lithium, the first approved mood-stabilizing drug, remains a first-line agent and sets the standard for efficacy against which other drugs are measured. It is antimanic, prevents relapse, and has modest efficacy for acute bipolar depression. One of the oldest drugs used for psychiatric illness, research continues to support its use. In most studies, lithium’s efficacy is equivalent to that of anticonvulsant mood stabilizers and SGAs. It is most effective for patients with few previous episodes, symptom-free interepisode remission, and a family history of bipolar disorder with good response to lithium. Evidence suggests genetic phenotypes that are more responsive to lithium. However, patients with rapid cycling are less responsive to lithium than to other mood-stabilizing drugs such as divalproex. Additionally, its efficacy for bipolar depression is less robust than for mania. It may also be less effective in mixed mood episodes (symptoms of mania and depression occurring simultaneously).

Evidence shows lithium’s effect on suicidal behavior is superior to that of other mood-stabilizing drugs. Lithium reduces the risk of deliberate self-harm or suicide by 70%.

Mechanism of Action Lithium’s mechanism of action is not well understood and is multimodal. Possibilities include altered ion transport, effects on neurotransmitter signaling, blocking adenyl cyclase, effects on inositol, neuroprotection or increased BDNF, and inhibition of second messenger systems.

Dosing and Monitoring Lithium is usually initiated at a dosage of 600 to 900 mg/day. Although it is commonly given in a divided dosage, once-daily dosing is recommended, especially with sustained-release formulations. Once-daily dosing can improve adherence and reduce renal side effects. Lithium has a narrow therapeutic index, meaning the toxic dosage is not much greater than the therapeutic dosage. Lithium requires regular serum concentration monitoring as a guide to titration and to minimize adverse effects. At least weekly monitoring is recommended until stabilized; then the frequency can be decreased. Well-maintained patients who tolerate lithium without difficulty can be monitored by serum concentration as infrequently as twice yearly. The dosage is titrated to achieve a serum lithium concentration of 0.6 to 1.4 mEq/L (mmol/L). Higher serum concentrations are required to treat an acute episode than to prevent relapse. Serum lithium above 0.8 mEq/L (mmol/L) may be more effective at preventing relapse than lower serum concentrations. The suggested therapeutic serum concentration range is based on a 12-hour postdose sample collection, usually a morning trough in patients taking more than one dose per day. At least 2 weeks at a suggested therapeutic serum concentration is required for an adequate trial. Table 39–5 shows pharmacokinetic parameters and desired serum concentrations of mood-stabilizing drugs. It is common for lithium to be combined with other mood stabilizers or antipsychotics to achieve more complete remission.

Adverse Effects The most common adverse effects are gastrointestinal (GI) upset, tremor, and polyuria, which are dose related. Nausea, dyspepsia, and diarrhea are minimized by coadministration with food, use of the sustained-release formulation, and giving smaller doses more frequently to reduce the amount of drug in the GI tract. Tremor is present in up to 50% of patients. In addition to these approaches, low-dose β-blockers, such as propranolol 20 to 60 mg/day, reduces tremor.

Lithium impairs the kidney’s ability to concentrate urine because of its inhibitory effect on vasopressin. This causes an increase in urine volume and frequency of urination and an increase in thirst. Polyuria and polydipsia occur in up to 70% of patients. A severe form of polyuria, when urine volume exceeds 3 L/day, is termed lithium-induced nephrogenic diabetes insipidus. It can be treated with hydrochlorothiazide or amiloride. If the former is used, the lithium dosage should be reduced by 33% to 50% to account for the drug–drug interaction that increases serum lithium and causes toxicity. Long-term lithium has been associated with structural kidney changes, such as glomerular sclerosis or tubular atrophy. Once-daily dosing of lithium is less likely to cause renal adverse effects than divided-daily dosing.

Lithium is concentrated in the thyroid gland and can impair thyroid hormone synthesis. Although goiter is uncommon, as many as 30% of patients develop at least transiently elevated thyroid-stimulating hormone. Lithium-induced hypothyroidism is not usually an indication to discontinue the drug. Patients can be supplemented with levothyroxine.

Other common adverse effects include poor concentration, acneiform rash, alopecia, worsening of psoriasis, weight gain, metallic taste, impaired glucose regulation, and benign leukocytosis. Lithium causes a flattening of the T wave of the electrocardiogram (ECG), considered benign and not clinically significant. Less commonly, it can cause or worsen arrhythmias.

Lithium and other mood-stabilizing drugs require baseline and routine laboratory monitoring to help determine medical appropriateness for initiation of therapy and monitoring of adverse effects. Guidelines for such monitoring are outlined in Table 39–6.

Acute lithium toxicity, which occurs at serum concentrations over 2 mEq/L (mmol/L), can be severe and life threatening, necessitating emergency treatment. Symptoms include severe vomiting and diarrhea, deterioration in motor coordination, including coarse tremor, ataxia, and dysarthria, and impaired cognition. In its most severe form, seizures, cardiac arrhythmias, coma, and kidney damage are reported. Treatment includes discontinuation of lithium, IV fluids to correct fluid and electrolyte imbalance, and osmotic diuresis or hemodialysis. In case of overdose, gastric lavage is indicated. Clinical symptoms continue after the serum concentration is lowered because clearance from the central nervous system (CNS) is slower than from serum. Factors predisposing to lithium toxicity include fluid and sodium loss from hot weather or exercise or drug interactions that increase serum lithium.

Drug Interactions Drug interactions involving lithium are common. Because lithium is not metabolized or protein bound, it is not associated with metabolic drug interactions that occur with other mood-stabilizing drugs. Common and significant drug interactions involve thiazide diuretics, nonsteroidal anti-inflammatory drugs, and angiotensin-converting enzyme (ACE) inhibitors. If a diuretic must be used with lithium and a thiazide is involved, the lithium dosage should be reduced by 33% to 50%.

Divalproex Sodium and Valproic Acid Divalproex sodium is composed of sodium valproate and valproic acid. The delayed-release and extended-release formulations are converted in the intestine into valproic acid (VPA), which is systemically absorbed. It is FDA approved for treatment of the manic phase of bipolar disorder. It is equal in efficacy to lithium and some other drugs for bipolar mania. It has utility in bipolar disorder with rapid cycling, mixed mood features, and substance abuse comorbidity. Although not FDA approved for relapse prevention, studies support its use, and it is widely prescribed for maintenance therapy. Divalproex can be used as monotherapy or in combination with lithium or an antipsychotic.

(Continued)
Mechanism of Action. The mechanism is not well understood. It is known to affect ion transport and enhance activity of γ-aminobutyric acid (GABA). Similar to lithium, it has possible neuroprotective effects through enhancement of BDNF.18

Dosing and Monitoring. Divalproex is initiated at 500 to 1000 mg/day, but studies indicate a therapeutic serum VPA concentration can be reached more quickly through a loading dose approach of 20 to 30 mg/kg/day. Using this approach, patients may respond with a significant reduction in symptoms within the first few days of treatment. The dosage is then titrated according to response, tolerability, and serum concentration. The most often referenced desired VPA serum concentration is 50 to 125 mcg/mL (347–866 μmol/L), but it is not unusual for patients to require more than 100 mcg/mL (693 μmol/L) for optimal efficacy.

</table>

<sup>a</sup>Screen for drug abuse and serum pregnancy.
<sup>b</sup>CBC with differential and platelets.
<sup>c</sup>Fasting glucose, serum lipids, weight.
<sup>d</sup>Lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, alkaline phosphatase.
<sup>e</sup>Serum creatinine, blood urea nitrogen, urinalysis, urine osmolality, specific gravity.
<sup>f</sup>Triiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.
<sup>g</sup>Serum sodium.
<sup>h</sup>Rashes, hair thinning, alopecia.
<sup>i</sup>Atypical antipsychotic: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy; cases of hyperlipidemia and diabetes reported.

Carbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline, and that subsequent monitoring be individualized by the clinician (eg, CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are less than 100,000/mm³ (100 × 10⁹/L), if WBC is less than 3000/mm³ (3 × 10⁹/L) or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in the elderly or those at risk for hyponatremia. Carbamazepine interferes with some pregnancy tests.

Lamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer’s guidelines. Serious dermatologic reactions have occurred within 2 to 8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dose escalation, or using doses exceeding the recommended titration schedule.

Lithium: Obtain baseline ECG for patients older than 40 years or if preexisting cardiac disease (benign, reversible T-wave depression can occur). Renal function tests should be obtained every 2 to 3 months during the first 6 months, then every 6 to 12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume more than 3 L/day, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, then every 6 to 12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1 to 2 months until thyroid function indices are within normal range, then monitor every 3 to 6 months.

Oxcarbazepine: Hyponatremia (serum sodium concentrations less than 125 mEq/L [mmol/L]) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (eg, diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (eg, confusion, headache, lethargy, and malaise). Hypersensitivity reactions have occurred in approximately 25% to 30% of patients with a history of carbamazepine hypersensitivity and requires immediate discontinuation.

Valproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3 to 6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are less than 100,000/mm³ (100 × 10⁹/L) or if prolonged bleeding time. Pancreatitis, hyperammonemias, encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.

Data from Refs. 14 and 38.
Some patients require high milligram dosages in order to reach a desired serum concentration. The suggested serum concentration range is based on trough values. Serum concentration monitoring is recommended at least every 2 weeks until stabilized, then less frequently. The extended-release formulation can be taken once daily (see Table 39–4). If the extended-release formulation is administered at night, a morning blood sampling is a peak, not a trough. The drug should be given in the morning so that blood sampling the following morning would be a trough value and more easily interpreted if the typical blood sampling time is in the morning. The systemic bioavailability of extended-release divalproex is about 15% less than that of the delayed-release formulation. Patients who have difficulty swallowing large tablets can use the sprinkle formulation. The immediate-release formulation, either capsules or syrup, is given three or four times per day.\(^\text{20}\)

**Adverse Effects.** The most common adverse effects are GI (loss of appetite, nausea, dyspepsia, diarrhea), tremor, and drowsiness. GI distress can be reduced by coadministration with food. The delayed-release and extended-release formulations are less likely to cause gastric distress than immediate-release valproic acid. Dosage reduction can reduce all of the common side effects. As with lithium, a low-dose β-blocker may alleviate tremor. Weight gain is common, occurring in up to 50% of patients.\(^\text{20}\)

Other less common adverse effects include alopecia or a change in hair color or texture. Hair loss can be minimized by supplementation with a vitamin containing selenium and zinc. Polycystic ovarian syndrome associated with increased androgen production is reported. Thrombocytopenia is common, and the platelet count should be monitored periodically. It is a dose-related adverse effect and usually asymptomatic, but the drug is usually stopped if the platelet count is less than 100 × 10^⁹/mm\(^3\) (100 × 10^⁸/L). More rare are hepatic toxicity and pancreatitis, which are not always dose related. Severe GI symptoms of hepatic or pancreatic toxicity include vomiting, pain, and loss of appetite. When these occur, the patient should be evaluated for possible hepatitis or pancreatitis. Divalproex has a wide therapeutic index. Acute toxicity for high dosages or overdosage is not life threatening.

**Drug Interactions.** Drug interactions involving divalproex are common. It is a weak inhibitor of some drug metabolizing liver enzymes and can affect metabolism of other drugs. These include other anticonvulsants and antidepressants. The interaction between divalproex and lamotrigine is significant. The risk of a dangerous rash caused by lamotrigine is increased when given concurrently with divalproex. When lamotrigine is added to divalproex, the initial lamotrigine dosage should be one-half the typical starting dosage, and lamotrigine should be titrated more slowly than usual. When divalproex is added to lamotrigine, the lamotrigine dosage should be reduced by 50%.\(^\text{21}\) Conversely, the metabolism of divalproex can be increased by enzyme-inducing drugs such as carbamazepine and phenytoin, but divalproex may simultaneously slow metabolism of the other agents.\(^\text{20}\)

**Carbamazepine** Although long used as a mood-stabilizer, only the extended-release formulation is FDA approved for treatment of bipolar disorder. Although it has efficacy for mood stabilization, it is less desirable as a first-line agent because of safety and drug interactions. It is reserved for patients who fail to respond to lithium or for patients with rapid cycling or mixed bipolar disorder. Carbamazepine can be used as monotherapy or in combination with lithium or an antipsychotic drug.\(^\text{22}\)

**Mechanism of Action.** The mechanism of action of carbamazepine is not well understood. It blocks ion channels and inhibits sustained repetitive neuronal excitation, but whether this explains its efficacy as a mood stabilizer is not known.\(^\text{22}\)

**Dosing and Monitoring.** Carbamazepine is initiated at 400 to 600 mg/day. The sustained-release formulation can be given in two divided doses. In addition to a formulation that is completely sustained release, an additional extended-release formulation contains a matrix of 25% immediate-release, 40% extended-release, and 35% enteric-release beads.\(^\text{22}\) The suggested therapeutic serum concentration is 4 to 12 mcg/mL (17-51 μmol/L). As with divalproex, some patients require high dosages to achieve a desired serum concentration and therapeutic effect. The dosage can be increased by 200 to 400 mg/day as often as every 2 to 4 days. Serum concentration monitoring is suggested at least every 2 weeks until stabilized.\(^\text{22}\)

**Adverse Effects.** The most common adverse effects are drowsiness, dizziness, ataxia, lethargy, and confusion. At mildly toxic levels, it causes diplopia and dysarthria. These can be minimized through dosage adjustments, use of sustained-release formulations, and giving more of the drug late in the day. GI upset is common. Carbamazepine has an antidiuretic effect similar to the syndrome of inappropriate antidiuretic hormone secretion and can cause hyponatremia. Mild elevations in liver enzymes can occur, but hepatitis is less common. Mild, dose-related leukopenia is not unusual and not an indication for discontinuation. More serious blood count abnormalities such as aplastic anemia and agranulocytosis are rare but life threatening.\(^\text{22}\) Suggested baseline and routine laboratory monitoring are reviewed in Table 39–6.

**Drug Interactions.** Carbamazepine induces hepatic metabolism of many drugs, including other anticonvulsants, antipsychotics, some antidepressants, oral contraceptives, and antiretroviral agents. Carbamazepine is an autoinducer (ie, it induces its own metabolism). The dosage may require an increase after 1 month or so of therapy because of this effect. Conversely, the metabolism of carbamazepine can be slowed by enzyme inhibiting drugs such as some antidepressants; macrolide antibiotics, including erythromycin and clarithromycin; azole antifungal drugs, including ketoconazole and itraconazole; and grapefruit juice. Carbamazepine should not be given concurrently with clozapine because of the additive risk of agranulocytosis.\(^\text{23}\)

**Lamotrigine** Lamotrigine is effective for maintenance treatment of bipolar disorder. It is more effective for depression relapse prevention than for mania relapse prevention. Its primary limitation as an acute treatment is the time required for titration to an effective dosage. In addition to maintenance monotherapy, it is sometimes used in combination with lithium or divalproex, although combination with divalproex increases the risk of rash, and lamotrigine dosage adjustment is required.\(^\text{21}\)

**Mechanism of Action.** The mechanism of action of lamotrigine appears to involve blockage of ion channels and effects on glutamate transmission, although the precise mechanism is not clear.\(^\text{21}\)

**Dosing and Monitoring.** Lamotrigine is initiated at 25 mg/day for 1 to 2 weeks, then increased in a dose-doubling manner every 1 to 2 weeks to a target of 200 to 400 mg/day. If lamotrigine is added to divalproex, the starting dosage is 25 mg every other day with a slower titration to reduce risk of rash. If divalproex is added to lamotrigine, the lamotrigine dosage should be reduced by 50% for the same reason. If lamotrigine therapy is interrupted for more than a few days, it should be restarted at the initial dosage and titrated. Serum concentration monitoring is not recommended.\(^\text{21}\)

**Adverse Effects.** The adverse effect of greatest significance is a maculopapular rash, occurring in up to 10% of patients.\(^\text{21}\) Although usually benign and temporary, some rashes can progress
Antipsychotic Drugs

The risk of rash is greater with a rapid dosage titration and when given concurrently with divalproex or other metabolic enzyme inhibitors. The risk is minimal when the dosage titration schedule is slow. Other side effects include dizziness, drowsiness, headache, blurred vision, and nausea. In contrast to other mood-stabilizing drugs such as lithium and divalproex, lamotrigine does not significantly influence body weight.

**Drug Interactions.** The mechanisms of drug–drug interactions involving lamotrigine are unclear. Lamotrigine’s primary route of metabolism is conjugative glucuronidation, although it is known to exhibit metabolic autoinduction. It is not significantly metabolized by CYP P450 enzymes. It does not affect drug metabolizing hepatic enzymes. Divalproex slows the rate of elimination of lamotrigine by about half, necessitating dosage reduction. Conversely, carbamazepine increases the rate of lamotrigine metabolism. Upward adjustment in dosage may be needed.21

**Oxcarbazepine** Oxcarbazepine is an analogue of carbamazepine, developed as an anticonvulsant. An advantage over carbamazepine is that routine monitoring of hematology profiles and serum concentrations is not indicated because it is less likely to cause hematologic abnormalities.24 Additionally, drug interactions are less significant, although it is a mild inducer of certain metabolic pathways. Vigilance for drug interactions is needed, especially with oral contraceptives. Oxcarbazepine appears in the most recent treatment algorithms for bipolar disorder,13 but clinical trial data are limited.25

**Adverse Effects.** Adverse effects include drowsiness, dizziness, GI upset, and hyponatremia, the latter two of which may be more likely than with carbamazepine.24

**Others** High-potency benzodiazepine agents such as clonazepam and lorazepam are used as adjunctive therapy, especially during acute mania, to reduce anxiety and improve sleep.26 As complementary or alternative medicines gain wider usage, omega-3 fatty acids have been used in mood disorders, but do not appear in treatment guidelines.

**Antipsychotic Drugs**

First-generation antipsychotics such as chlorpromazine and haloperidol have long been used in the treatment of acute mania. SGA drugs, including aripiprazole, asenapine, olanzapine, quetiapine, risperidone, and ziprasidone, are approved for the treatment of bipolar mania or mixed mood episodes as monotherapy or in combination with mood stabilizers.13 Aripiprazole, olanzapine, and quetiapine are approved for maintenance therapy for prevention of manic relapse. The combination of olanzapine and fluoxetine is approved for treatment of acute bipolar depression. Quetiapine is approved as monotherapy for acute bipolar depression and as adjunctive therapy with lithium or divalproex for prevention of bipolar depression relapse. Lurasidone is approved as monotherapy and as adjunctive therapy with lithium or divalproex for acute bipolar depression. Approval of antipsychotic drugs in patients with bipolar disorder applies without regard to presence of psychosis. In comparative studies, SGAs are equivalent or superior in efficacy to lithium and divalproex for treatment of acute mania. Treatment guidelines include antipsychotic drugs as first-line therapy.13 The combination of mood stabilizers and antipsychotics is more likely to achieve remission than monotherapy. Quetiapine data in relapse prevention of both manic and bipolar depression episodes favored combination therapy over mood-stabilizer monotherapy.27

The mechanisms of action, usual dosages, pharmacokinetics, adverse effects, and drug interactions involving antipsychotic drugs are discussed in detail in the chapter on schizophrenia. Dosages in bipolar disorder are similar to those used in schizophrenia. Higher dosages are often required to treat an acute episode. The recommended dosage of aripiprazole for bipolar disorder is 20 to 30 mg/day, somewhat higher than the average dosage used in schizophrenia.29 The recommended dosage for quetiapine in treatment of acute bipolar depression is 300 mg/day, less than the 600 mg/day recommended in acute mania.29

SGAs are less likely than FGAs to cause neurologic side effects, especially movement abnormalities. SGAs are more likely to cause metabolic side effects, such as weight gain, glucose dysregulation, and dyslipidemia.30 Among SGAs approved for treatment of bipolar disorder, olanzapine is most likely to cause metabolic side effects. Asenapine, lurasidone, quetiapine, and risperidone cause less metabolic effects than olanzapine. Aripiprazole, lurasidone, and ziprasidone are least associated with effects on weight, glucose, and lipids.

**Antidepressants**

Treatment of depressive episodes in patients with bipolar disorder presents a particular challenge because of risk of a drug-induced mood switch to mania. The FDA requires the product label of all antidepressants to contain language about the potential risk of inducing a mood switch to mania. Most research shows no advantage for adjunctive antidepressant use compared with mood-stabilizer therapy alone.13,25 Treatment guidelines and current FDA approvals indicate lithium and quetiapine as first-line therapy.13 The approval of lurasidone for acute bipolar depression is recent, thus it is not widely included in first-line recommendations. When usual treatment fails, evidence supports use of antidepressants.13,15

Guidelines agree that when antidepressants are used, they should be combined with a mood stabilizer to reduce risk of mood switch. The question of which antidepressant drugs are less likely to cause a mood switch is not resolved, but tricyclic antidepressants are thought to carry greater risk. A comparison of venlafaxine, sertraline, and bupropion as adjunctive therapy to a mood stabilizer showed venlafaxine with highest risk of a mood switch to mania or hypomania and bupropion with the least.31

**Special Populations**

- Assessment and management by appropriate psychiatric specialists is important for special populations, such as pediatric, geriatric, and pregnant patients.

**Pediatrics**

Evidence regarding treatment of bipolar disorder in children and adolescents is more limited than in adults. Children and adolescents are sensitive to medication side effects, including metabolic side effects of SGAs. With these caveats, evidence supports use of mood stabilizers and SGAs in children and adolescents with bipolar disorder. Lithium is FDA approved for treatment of bipolar disorder in children and adolescents as young as age 12. Aripiprazole, olanzapine, quetiapine, and risperidone are FDA approved in children and adolescents as young as age 10.13,12

Initial dosages in the pediatric population are lower than in adults. Metabolic elimination rates of many drugs are increased in children, so they may actually require higher dosages on a weight-adjusted basis. Dosages are titrated carefully according to response and tolerability.

Children and adolescents are especially likely to experience weight gain from SGAs.33 Cognitive toxicity, manifested as confusion, memory or concentration impairment, or impaired
learning, is difficult to detect and is a consideration in the pediatric population so that intellectual and educational development is not hindered.

For comorbid bipolar disorder and attention-deficit/hyperactivity disorder when stimulant therapy is indicated, treatment of mania is recommended before starting the stimulant to avoid exacerbation of mood symptoms.

Geriatrics

Treatment of older adults with bipolar disorder requires care because of increased risks associated with medical conditions and drug–drug interactions. General medical conditions, including endocrine, metabolic, or infectious diseases, can mimic mood disorders. Patients should be evaluated for such medical illnesses that cause or worsen mood symptoms. As physiologic systems change with aging, elimination of drugs is slowed. Examples are slowed renal elimination of lithium and slowed hepatic metabolism of carbamazepine and valproic acid. As a result, dosages required for therapeutic effect are lower in geriatric patients. Also, changes in membrane permeability increase risk of CNS side effects. Increased frequency of patient monitoring is required, including serum drug concentration monitoring.

Vigilance for drug–drug interactions is required because of more medications prescribed to older adults and enhanced sensitivity to adverse effects. Pharmacokinetic interactions include metabolic enzyme induction or inhibition and protein binding displacement interactions (eg, divalproex and warfarin). Pharmacodynamic interactions include additive sedation and cognitive toxicity, which increases risk of falls and other impairments.

Pregnancy and Postpartum

Treatment of bipolar disorder during pregnancy is fraught with controversy and conflicting recommendations. The key issue is the relative risk of teratogenicity with drug use during pregnancy versus risk of bipolar relapse without treatment with consequent harm to both patient and fetus. Therapeutic judgments depend on the history of the patient and whether the pregnancy is planned or unplanned. Treatment is best managed when pregnancy is planned. Clinicians should discuss the issue with every patient with bipolar disorder who is of childbearing potential. A pregnancy test should be obtained before initiating therapy. For a patient with severe illness, a history of multiple mood episodes, rapid cycling, or suicide attempts, discontinuing treatment, even for a planned pregnancy, is unwise. For a patient with a remote history of a single mood episode with subsequent long stability and contemplating pregnancy, the answer is less clear. Patients should be provided clear and reliable information about risks versus benefits of stopping or continuing therapy so they can make an informed decision. Patients who decide to discontinue medication before pregnancy should taper medication slowly.

Lithium administration during the first trimester is associated with Ebstein anomaly, a downward displacement of the tricuspid valve. Although more likely to occur in children of patients who took lithium during pregnancy, the absolute risk is small, around 0.1%. Pharmacokinetic handling of lithium changes as pregnancy progresses. Renal lithium clearance increases, which requires a dosage increase to maintain a therapeutic serum concentration. It is advisable to decrease or discontinue lithium at term or onset of labor to avoid toxicity postpartum when there is a large reduction in fluid volume.

Lithium can cause hypotonicity and cyanosis in the neonate, termed the “floppy baby” syndrome. Most data indicate normal neurobehavioral development when these symptoms resolve.

Lithium is readily transferred via breast milk. Breastfeeding is not advised for patients taking lithium.

Valproic acid and carbamazepine are human teratogens. Neural tube defects such as spina bifida occur in up to 9% of infants exposed during the first trimester. The risk of neural tube defects is related to exposure during the third and fourth weeks of gestation. As such, women with unplanned pregnancies may not know they are pregnant until after the risk of exposure has occurred. Carbamazepine can cause fetal vitamin K deficiency. Vitamin K is important for facial growth and for clotting factors. The risk of facial abnormalities is increased with carbamazepine and VPA, and neonatal bleeding is increased in infants of mothers who are treated with carbamazepine during pregnancy.

Fewer data are available on other anticonvulsant mood-stabilizing drugs. Lamotrigine may be associated with an increased risk of oral clefts.

The FGAs have been available for many years, and more data are available on their use in pregnancy compared with SGAs, but guidelines for bipolar disorder do not otherwise support FGAs as an initial choice.

Use of antidepressant drugs during pregnancy is discussed in the chapter on depression.

OUTCOME EVALUATION

Assessment of Therapeutic Effects

Effective interviewing skills and a therapeutic relationship with the patient are essential to assessing response. Understand the particular symptom profile and needs of individual patients. These are the primary therapeutic monitoring parameters. In addition to clinical interview, some clinicians use symptom rating scales such as the Young Mania Rating Scale (YMRS) for mania and the Hamilton Depression Rating Scale (Ham-D, discussed in the chapter on depression). The YMRS is composed of 11 items based on a patient’s perception over the preceding 48 hours. Adjunctive information is obtained from clinical observations. The scale takes about 15 to 30 minutes to administer.

Patient Encounter, Part 4: Outcome Evaluation

After an initial assessment, including evaluation of potential suicidality, support systems, and need for inpatient versus outpatient treatment, Joan was hospitalized briefly and then followed in the community on medication as well as psychotherapy. Joan has discontinued her use of alcohol and is now attending Alcoholics Anonymous meetings along with her father. She has also stopped smoking marijuana. Her school performance has returned to normal, and her grades are improving. Joan has responded well to treatment with divalproex 500 mg by mouth twice daily. Recent serum valproic acid levels have stabilized at 80 mcg/mL (554 μmol/L). She now returns to the clinic for routine follow-up. Joan initially complained about mild headaches and nausea which have subsequently resolved, and she has tolerated the divalproex well. However, she now asks how long she must take this medication since she is feeling completely well.

How would you assess therapeutic and adverse effects of treatment for this patient?

How would you educate the patient regarding the need for continued maintenance treatment?
Patient Care Process

**Patient Assessment:**
- Assess the patient’s symptoms and review the history. Review the family history, including the history of response to treatment by family members.
- Obtain an initial medical evaluation to rule out other causes of mood episodes.
- Evaluate physiologic parameters that may influence pharmacokinetics.

**Therapy Evaluation:**
- Obtain a thorough medication use history, including present and past prescription and nonprescription drugs, the patient’s self-assessment of response and side-effects, alcohol, tobacco, caffeine, illicit substances, herbal products, dietary supplements, allergies, and adherence.

**Care Plan Development:**
- Develop a plan for monitoring therapeutic outcomes, focusing on the individual symptom profile and level of function of the patient. Include a plan for dosage adjustments or alternate therapy if the patient fails to respond adequately. Include serum drug concentration monitoring as appropriate.
- Develop a monitoring plan for drug side effects. Include measures to prevent side effects as well as management if they occur. Include appropriate laboratory measures.
- Determine the role of nonpharmacologic therapy and how it is to be integrated with drug therapy.
- Educate the patient on the nature of bipolar disorder, its treatment, and what to expect with regard to response and side effects, and stress the need for adherence to treatment even when feeling well.
- Encourage a healthy lifestyle, including eliminating or stopping substance abuse, smoking cessation, and encouraging proper nutrition and exercise.

**Follow-Up Evaluation:**
- See the patient daily if hospitalized or weekly if an outpatient to assess efficacy and safety until stabilized. Utilize the clinical interview, physical exam, and lab tests.
- Once stabilized, follow up at decreased frequency, every 3 to 6 months. Use the same parameters and check for new drugs or drug-drug interactions.

Check serum concentrations of mood-stabilizing drugs as a guide to dosage adjustment for optimal efficacy. The frequency of follow-up visits depends on response, tolerability, and adherence.

**Assessment of Adverse Effects**
Adverse effects cause more nonadherence than any other factor. Monitor patients regularly for adverse effects and health status, especially because mood stabilizers and antipsychotics commonly cause metabolic side effects such as weight gain. Repeat laboratory tests for renal and thyroid function for patients taking lithium and hematology and liver function for patients taking carbamazepine or divalproex. Annual measurement of serum lipase is advisable for patients taking divalproex. More specific discussion of metabolic side effect monitoring of patients taking SGAs is provided in the chapter on schizophrenia.

**Patient Education**
*Key Concept* Education of the patient regarding benefits and risks of drug therapy and the importance of adherence to treatment must be integrated into pharmacologic management. This is important because responsiveness to treatment declines as the number of mood episodes increases. Discuss the nature and chronic course of bipolar disorder and risks of repeated relapses. Help patients understand treatment is not a cure but that many patients enjoy symptom-free or nearly symptom-free function. Make it clear that long-term recovery is dependent on adherence to pharmacologic and nonpharmacologic treatment. Explain the purpose of medication, common side effects to expect, and how to respond to side effects. Provide the patient and family with written information about indications, benefits, and side effects. Discuss less frequent but more dangerous side effects of drugs, and give written instructions on seeking medical attention immediately should they occur.

### Abbreviations Introduced in This Chapter

- 5-HT: 5-hydroxytryptamine
- Abd: Abdomen
- ACE: Angiotensin-converting enzyme
- ARB: Angiotensin receptor blocker
- BDNF: Brain-derived neurotrophic factor
- BP: Blood pressure
- CBC: Complete blood count
- CBT: Cognitive-behavioral therapy
- CN: Cranial nerve
- CNS: Central nervous system
- DA: Dopamine
- DSM-5: Diagnostic and Statistical Manual of Mental Disorders, 5th edition
- ECG: Electrocardiogram
- ECT: Electroconvulsive therapy
- Exts: Extremities
- FDA: Food and Drug Administration
- FGA: First-generation antipsychotic
- fMRI: Functional magnetic resonance imaging
- FOI: Flight of ideas
- GABA: γ-aminobutyric acid
- GI: Gastrointestinal
- Ham-D: Hamilton Depression Rating Scale
- β-HCG: Beta-human chorionic gonadotropin
- HIV: Human immunodeficiency virus
- JVD: Jugular venous distention
- LMP: Last menstrual period
- MDD: Major depressive disorder
- MRI: Magnetic resonance imaging
- NE: Norepinephrine
- P: Pulse
Pupils equal round and reactive to light and accommodation

PET Positron emission tomography
RR Respiration rate
SGA Second-generation antipsychotic
T Temperature
THC Tetrahydrocannabinol, psychoactive Substance in marijuana
VPA Valproic acid
YMRS Young Mania Rating Scale

REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:
1. Describe pathophysiology of generalized anxiety, panic, and social anxiety disorders (SAD).
2. List common presenting symptoms of generalized anxiety, panic, and SAD.
3. Identify the desired therapeutic outcomes for patients with generalized anxiety, panic, and SAD.
4. Discuss appropriate lifestyle modifications and over-the-counter medication use in these patients.
5. Recommend psychotherapy and pharmacotherapy interventions for patients with generalized anxiety, panic, and SAD.
6. Develop a monitoring plan for anxiety patients placed on specific medications.
7. Educate patients about their disease state and appropriate lifestyle modifications, as well as psychotherapy and pharmacotherapy for effective treatment.

INTRODUCTION

Anxiety disorders are among the most frequent mental disorders encountered by clinicians. All anxiety disorders share features of fear and anxiety that differ from developmentally normative fear or anxiety by being excessive, persistent, and resulting in behavioral disturbances.

Anxiety disorders are often missed or attributed incorrectly to other medical illnesses, and most patients are treated inadequately. The burden of diagnosis usually falls to primary care clinicians, to whom most patients present in the context of other complaints. Untreated anxiety disorders may result in increased health care utilization, morbidity and mortality, and a poorer quality of life.

EPIDEMIOLOGY AND ETIOLOGY

Epidemiology

Prevalence

The lifetime prevalence of anxiety disorders collectively is 28.8% with specific phobia (12.5%) and social anxiety disorder (SAD) (12.1%) being the most common. Data from the National Comorbidity Survey, Revised (NCS-R) estimate the lifetime prevalence of generalized anxiety disorder (GAD) for those 18 years of age and older to be 5.7%, and rates for panic disorder (PD), 4.7%. Anxiety disorders are more prevalent among women than men (2:1). Prevalence rates across the anxiety spectrum increase from the younger age group (18–29 years) to older age groups (30–44 and 45–59 years); however, rates are substantially lower for those older than age 59 years.

Course of Illness

PD and GAD have a median age of onset of 24 and 31 years, respectively, whereas SAD develops earlier (median age 13 years). Although GAD and PD may not manifest fully until adulthood, as many as half of adult anxiety patients report sub-threshold symptoms during childhood.

Anxiety disorders are chronic, and symptoms tend to wax and wane, with fewer than one-third of patients experiencing spontaneous symptom remission. The risk for relapse and recurrence of symptoms is also high for anxiety disorders. In a 12-year follow-up study of anxiety disorder patients, recurrence rates ranged from 58% of PD and GAD patients to 39% of SAD patients.

Remission, if achieved with treatment, is most likely to occur within the first 2 years of an index episode. Similarly, the highest rates of relapse are within the same timeframe. This suggests that many patients need ongoing maintenance treatment. Rates of remission and relapse do not appear to vary by sex; however, one study reported that women with PD without agoraphobia were three times more likely than men to relapse. Patients with anxiety disorders spend a significant portion of time “being ill” during a particular episode, ranging from 41% to 80% of the time. Anxiety disorders are associated with impaired psychosocial functioning and a compromised quality of life. Appropriate treatment improves overall quality of life and psychosocial functioning.

Comorbidity

More than 90% of individuals with an anxiety disorder have a lifetime history of one or more other psychiatric disorders. Depression is the most common comorbidity, followed by...
alcohol and substance use disorders, as well as other co-occurring anxiety disorders, especially GAD and PD. Generally, the onset of SAD and GAD symptoms precedes major depressive disorder (MDD), but there is an equal chance of PD onset before, during, or after MDD. Comorbid psychiatric illness is associated with lower rates of remission and higher rates of relapse. Both disorders must be treated appropriately.

**Etiology**

Both genetic and psychosocial factors appear to play a role in the initiation and expression of anxiety disorders. Documentation of moderate genetic risk has been identified for all anxiety disorders, although conflicting data exist. No definitive gene or set of genes has been identified as causative for a specific anxiety disorder. Additionally, it is unclear if anxiety disorders share common genetic risk factors. Genetic overlap may exist between GAD and PD and, to a lesser extent, SAD.

Genetics may create a vulnerable phenotype for an anxiety disorder, and an individual’s life stressors and means of coping with the stress may play a role in precipitation and continued expression of the anxiety disorder. Some researchers believe that stressful life events may have a strong role in the onset of anxiety disorders, especially in GAD and PD. It has been reported that those experiencing one or more negative life events have a threefold increased chance of developing GAD. Similar findings have been reported with PD.

**PATHOPHYSIOLOGY**

The thalamus and amygdala are important in the generation of a normal fear response and play a central role in most anxiety disorders (Figure 40–1). The thalamus provides the first real processing region to organize sensory data obtained from the environment. It passes information to higher cortical centers for finer processing and to the amygdala for rapid assessment of highly charged emotional information. The amygdala provides emotional valence or the emotional importance of the information. This helps the organism to act quickly on ambiguous but vital events. The cortex then performs a more detailed analysis and sends updates to the amygdala for comparison and any needed course corrections, thus enabling a decision on a course of action.

Anxiety becomes an anxiety disorder when the fear-response system leads to maladaptive behavior or distress. Anxiety can become independent of stimuli as in PD, be associated with benign stimuli as in phobias, or continue beyond the stimulus duration as in GAD.

Direct and indirect connections to the reticular activating system (RAS), a region spanning the medulla, pons, and midbrain, help to regulate arousal, vigilance, and fear. These connections are modulated by serotonin (5-HT) and norepinephrine (NE), which have their primary origins in the RAS. The amygdala sends projections to the hypothalamus, thus influencing the autonomic nervous system to affect heart rate, blood pressure, and stress-associated changes. It also influences the hypothalamic–pituitary–adrenal (HPA) axis, leading to a cascade of stress hormones. One such hormone is cortisol, which, if elevated for prolonged periods, can damage the brain and other organs.

**Noradrenergic System**

Norepinephrine-producing cells reside primarily in a region of the brain called the locus ceruleus (LC). Increased activity in this region is associated with an increase in arousal, anxiety, and panic. Drugs such as yohimbine that increase activity in the LC can be anxiogenic; drugs that decrease activity in the LC appear to improve anxiety. Furthermore, dysregulation of this region is implicated by elevated levels of NE or its metabolites in subjects with GAD, PD, and specific phobias.

**Serotonergic System**

The raphe nuclei and the resident cell bodies of 5-HT-producing neurons have a complicated role related to anxiety symptoms. Activity of 5-HT cells in the raphe nuclei over time inhibits firing of noradrenergic cells in the LC. Other influences include their ability to regulate cells in the prefrontal cortex and amygdala.
Perhaps the strongest evidence for the involvement of the serotonergic system is the success of serotonin reuptake inhibitors in treatment of anxiety disorders.\textsuperscript{13}

\textbf{γ-Aminobutyric Acid}

\textit{γ}-Aminobutyric acid (GABA) plays a complex role as an inhibitor neurotransmitter with nonspecific effects. GABA-ergic drugs reduce anxiety, but the lack of a specific target for their effect leads to multiple undesirable effects. Current research is focused on defining receptor subtypes that may allow for greater specificity in targeting anxiety symptoms.\textsuperscript{14}

\textbf{Hypothalamic–Pituitary–Adrenal Axis}

The HPA axis provides a critical mechanism for regulation of the stress response and its effects on the brain and other organ systems. Several important hormones, including corticotropin-releasing hormone and cortisol, are involved in this pathway. These hormones regulate the effects of anxiety on the body and provide positive feedback to the brain. A cycle of anxiety and sensitization by such feedback could, if unchecked, result in escalation of symptoms. Neuropeptides may provide one mechanism to balance positive and negative feedback, helping to minimize such escalation.

\textbf{Neuropeptides}

Several neuropeptides (e.g., neuropeptide Y [NPY], substance P, and cholecystokinin) are under investigation for their role in anxiety disorders. NPY appears to reduce the effect of stress hormones and inhibit activity of the LC. Both mechanisms may contribute to the anxiolytic properties seen experimentally. Substance P may have anxiolytic and antidepressant properties partly because of its effects on corticotropin-releasing hormone.\textsuperscript{15}

\textbf{Patient Encounter 1, Part 1}

A 24-year-old woman presents to the primary care clinic with complaints of fatigue, joint pain, insomnia, irritability, and daily headaches. She admits to having one to two drinks at night to help with her sleep and “turn her mind off”. She states she panicked at the beginning of her economics exam and ran from the room. She states she is overwhelmed with her coursework in an MBA program, and her relationship with her boyfriend has been tumultuous over the past several months. Her medical history is positive for depression and migraine headaches.

\textbf{Meds:} Topiramate 50 mg/day

\textit{What manifestations described above are suggestive of an anxiety disorder?}

\textit{What additional information do you need to establish a diagnosis and develop a treatment plan?}

\textit{What other diagnoses should be considered in your differential diagnosis?}

\textit{Could her medication be contributing to her symptoms?}

### Pharmacologic Therapy

Antidepressants, benzodiazepines, pregabalin, buspirone, hydroxyzine, and the second-generation antipsychotics (SGAs) have controlled clinical trial data supporting their use in GAD. **KEY CONCEPT** Antidepressants are the drugs of choice for chronic GAD because of a tolerable side-effect profile; no risk for dependency; and efficacy in common comorbid conditions, including depression, panic, obsessive-compulsive disorder (OCD), and SAD. Benzodiazepines remain the most effective and commonly used treatment for short-term management of anxiety when immediate relief of symptoms is desired. They are also recommended for intermittent or adjunctive use during GAD exacerbation or for sleep disturbance during the initiation of antidepressant treatment. Buspirone and pregabalin are alternative agents for patients with GAD without depression. Hydroxyzine is usually adjunctive and is less desirable for long-term treatment because of side effects, eg, sedation and anticholinergic effects.

Patients with GAD should be treated to symptom remission. Although supporting data are lacking, recent guidelines recommend continuing treatment for 1 year. Continuation of antidepressant therapy after acute response significantly decreases the risk of relapse (odds ratio, 0.2 [0.15–0.26]). An algorithm for the pharmacologic management of GAD is shown in Figure 40–2.

### Antidepressants

Antidepressants (Table 40–3) reduce the psychic symptoms (eg, worry and apprehension) of anxiety with a modest effect on autonomic or somatic symptoms (eg, tremor, rapid heart rate, and/or sweating). All antidepressants evaluated provide a similar degree of anxiety reduction. The onset of anxiolytic effect is delayed 2 to 4 weeks. Selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) are usually preferred over tricyclic antidepressants (TCAs) because of improved safety and tolerability. Selection of a specific antidepressant generally is based on history of prior response, side effect and drug interaction profile (see Chapter 38), cost, or formulary availability.

Antidepressants modulate synaptic 5-HT, NE, and/or dopamine (DA) reuptake and receptor-activated neuronal signal transduction. These intracellular changes modify the expression of genes and proteins important in stress response (eg, glucocorticoid...
receptors, brain-derived neurotrophic factor, corticotropin-releasing hormone). Activation of these “stress-adapting” pathways may improve both somatic and psychic symptoms of anxiety.24

Serotonin Norepinephrine Reuptake Inhibitors Venlafaxine and duloxetine are approved by the Food and Drug Administration (FDA) for the treatment of GAD. They alleviate anxiety with and without depression and have improved tolerability over TCAs. Venlafaxine is effective at doses 75 to 225 mg/day and maintains response with extended treatment.18 It is also effective for GAD in children and adolescents.19 The most common side effects reported in patients with GAD are nausea, somnolence, dry mouth, dizziness, sweating, constipation, and anorexia.18,23

Duloxetine is similarly effective and tolerated as venlafaxine.25 For patients with concurrent pain syndromes, duloxetine has been found to improve anxiety, pain, and functional impairment more than placebo.26 Newer SNRIs, milnacipran, levomilnacipran, and vortioxetine have not been evaluated in the treatment of GAD.

Selective Serotonin Reuptake Inhibitors The SSRIs paroxetine, escitalopram, and sertraline have been shown to be significantly more effective than placebo in reducing anxiety symptoms in adults with GAD. Response rates range from 56% to 68% during acute treatment, with remission achieved in approximately one-third of patients.27–30 Common side effects include somnolence, headache, nausea, dry mouth (paroxetine), diarrhea (sertraline), sweating (sertraline), decreased libido, ejaculation disorder, anorgasmia, and asthenia.

SSRI therapy is better tolerated than TCAs, and tolerability is similar to that of venlafaxine. Citalopram is efficacious in the treatment of GAD in the elderly.31 The SSRIs, sertraline, fluoxetine, and fluvoxamine have demonstrated benefits in children and adolescents with GAD and are the preferred pharmacologic treatment in this population.19

Tricyclic Antidepressants Imipramine treatment of GAD results in a higher rate of remission of anxiety symptoms than treatment with trazodone or diazepam.18 Both antidepressants were more effective than diazepam or placebo in reducing psychic symptoms of anxiety. TCA use is limited by bothersome adverse effects (eg, sedation, orthostatic hypotension, anticholinergic effects, and weight gain). TCAs have a narrow therapeutic index and are lethal in overdose because of atrioventricular block.

Novel Antidepressants Mirtazapine, an α-2 adrenergic antagonist and postsynaptic serotonin (5-HT₁, 5-HT₂) receptor antagonist, is an effective antidepressant but has not been extensively evaluated in anxiety disorders. One open-label study found 12-week treatment of GAD with mirtazapine 30 mg to be efficacious and well tolerated.14 It is not associated with sexual dysfunction, but does have a propensity to cause sedation and weight gain. Bupropion, a dopamine and norepinephrine reuptake-inhibitor, lacks the common antidepressant side effects of weight gain and sexual dysfunction. Bupropion has not been studied or used extensively in anxiety disorders owing to its stimulating effects that would be expected to worsen anxiety symptoms. However, a small controlled trial comparing bupropion XL with escitalopram found bupropion to have comparable anxiolytic efficacy and tolerability.14 Vilazodone, a SSRI, and 5-HT₁A receptor partial agonist has not been evaluated in anxiety disorders.

Benzodiazepines

Benzodiazepines are recommended for acute treatment of GAD when short-term relief is needed, as an adjunct during initiation of antidepressant therapy, or to improve sleep.18 Benzodiazepine treatment results in a significant improvement in 65% to 75% of GAD patients, and most of the improvement occurs in the initial 2 weeks. They are more effective for somatic symptoms than psychic symptoms. Major benzodiazepine disadvantages are lack of effectiveness for depression; risk for dependency and abuse; and potential interdose rebound anxiety, especially with short-acting benzodiazepines. They should be avoided in older adults and patients with current or past chemical dependency.

Benzodiazepines enhance transmission of the inhibitory neurotransmitter GABA through interaction with the GABA₆-receptor complex.17,18 Only 7 of the 13 currently marketed benzodiazepines are approved by the FDA for the treatment of anxiety disorders (Table 40–4). All benzodiazepines are expected to provide equivalent benefit when given in comparable doses. They differ substantially in their pharmacokinetic properties and potency for the GABA₆-receptor.

Benzodiazepines are metabolized by hepatic oxidation (cytochrome P450 3A4) and glucuronide conjugation. Because lorazepam and oxazepam bypass hepatic oxidation and are conjugated only, they are preferred agents for patients with reduced hepatic function secondary to aging or disease (eg, cirrhosis; hepatitis B or C from intravenous drug use). Many benzodiazepines are metabolized to long-acting metabolites (see Table 40–4) that

a Food and Drug Administration (FDA) approved for use in generalized anxiety disorder.

b FDA approved for use in panic disorder.

c CYP2C19 genetic polymorphisms resulting in little or no enzyme activity are present in 15% to 20% of Asians and 3% to 5% of blacks and whites, resulting in reduced clearance of desmethyldiazepam.

Data from Refs. 32 and 33.
provide long-lasting anxiety relief. Drugs that either inhibit or induce CYP450 isozymes or glucuronidation can cause drug interactions (Table 40–5).

The most common side effects of benzodiazepine therapy include central nervous system (CNS) depressive effects (eg, drowsiness, sedation, psychomotor impairment, and ataxia) and cognitive effects (eg, poor recall and anterograde amnesia). Anterograde amnesia is more likely with high-potency benzodiazepines such as alprazolam. Some patients also may be disinhibited and experience confusion, irritability, aggression, and excitement. Discontinuation of benzodiazepines may be associated with withdrawal, rebound anxiety, and a high rate of relapse. Higher doses of benzodiazepines and a longer duration of therapy increase the severity of withdrawal and risk of seizures after abrupt or rapid discontinuation. Patients should be tapered rather than discontinued abruptly from benzodiazepine therapy to avoid withdrawal symptoms. The duration of the taper should increase with extended duration of benzodiazepine therapy. For example, patients on benzodiazepine therapy for 2 to 6 months should be tapered over 2 to 8 weeks, but patients receiving 12 months of treatment should be tapered over 2 to 4 months. A general approach to the taper is to reduce the dose by 25% every 5 to 7 days until reaching half the original dose and then decreasing by 10% to 12% per week until discontinued. Patients should expect minor withdrawal symptoms and discomfort even when tapering. Rebound symptoms (eg, return of original symptoms at increased intensity) are transient. The patient should be educated that rebound anxiety is not a relapse. Relapse or recurrence of anxiety may occur in as many as 50% of patients discontinuing benzodiazepine treatment. It is unclear if this relapse rate represents an inferiority of benzodiazepines or supports the chronic nature of GAD.

**Pregabalin**

Pregabalin is a calcium channel modulator, and its anxiolytic properties are attributed to its selective binding to the α-2-delta subunit of voltage-gated calcium channels. In a 4-week controlled trial versus alprazolam and placebo, pregabalin was effective for both somatic and psychic symptoms of anxiety with onset of effect similar to that of alprazolam. Compared with venlafaxine and placebo, pregabalin was safe, well tolerated, and efficacious in GAD, and results were seen 1 week sooner than with venlafaxine. Pregabalin reduced the risk of relapse versus placebo in a 26-week relapse prevention trial. It has a short elimination half-life and must be dosed two to three times daily. It is excreted renally with a low risk of drug–drug interactions. Pregabalin is a schedule V controlled substance owing to a propensity to cause euphoria, and it may cause withdrawal symptoms if discontinued abruptly. It should be used cautiously in patients with a current or past history of substance abuse. It is not beneficial for depression or other anxiety disorders.

**Alternative Agents**

Hydroxyzine, buspirone, and SGAs are alternative agents. Hydroxyzine may be effective for acute reduction of somatic symptoms of anxiety but not for psychic features of anxiety, depression, or other common comorbid anxiety disorders. Buspirone, a 5-HT1A partial agonist, is thought to exert its anxiolytic effects by reducing presynaptic 5-HT firing. Unlike benzodiazepines, it does not have abuse potential, cause withdrawal reactions, or potentiate alcohol and sedative-hypnotic effects. It has a gradual onset of action (ie, 2 weeks) and does not provide immediate anxiety relief. Data are inconsistent regarding its efficacy in chronic GAD or GAD with comorbid depression.
It may be less effective in patients who have been treated previously (4 weeks–5 years) with benzodiazepines. It is unclear if buspirone should be initiated at 7.5 mg twice daily and titrated in 5-mg/day increments (every 2–3 days) to a usual target dose of 20 to 30 mg/day. The maximum daily dose is considered to be 60 mg/day. Buspirone is well tolerated and does not cause sedation. The most common side effects include dizziness, nausea, and headaches. Drugs that inhibit CYP3A4 (eg, verapamil, diltiazem, itraconazole, fluvoxamine, and erythromycin) can increase buspirone levels. Enzyme inducers (eg, rifampin) can decrease buspirone levels. Buspirone may increase blood pressure when coadministered with a monoamine oxidase inhibitor (MAOI).

The SGAs, quetiapine, olanzapine, and risperidone have demonstrated benefit in GAD. In three large placebo controlled trials, quetiapine in daily doses of 50 to 300 mg resulted in 26% greater likelihood of treatment response (effect size, ~0.3). Quetiapine had similar outcomes to paroxetine 20 mg/day and escitalopram 10 mg/day. Risperidone and olanzapine may improve treatment outcomes in patients with inadequate response to initial pharmacotherapy. SGAs are associated with a risk of weight gain, sedation, fatigue, and extrapyramidal symptoms in anxiety patients.

### Outcome Evaluation
Assess patients for improvement of anxiety symptoms and return to baseline occupational, social, and interpersonal functioning. With effective treatment, patients should have no or minimal symptoms of anxiety or depression. With initiation of drug therapy, evaluate patients frequently for tolerability and response. Monitor for suicidal ideation and behaviors for children, adolescents, and young adults (24 years of age or less) initiated on antidepressants. Increase the dose in patients exhibiting a partial response after 2 to 4 weeks on an antidepressant or 2 weeks on a benzodiazepine. Individualize the duration of treatment as some patients require up to 1 year of treatment.

### Treatment: Panic Disorder

#### Desired Outcomes
The main objectives of treatment are to reduce the severity and frequency of panic attacks, reduce anticipatory anxiety and agoraphobic behavior, and minimize symptoms of depression or other comorbid disorders. The long-term goal is to achieve and sustain remission and restore overall functioning.

#### General Approach to Treatment
Treatment options include medication, psychotherapy, or a combination of both. In some cases, pharmacotherapy will follow psychotherapy treatments when full response is not realized. Patients with panic symptoms without agoraphobia may respond to pharmacotherapy alone. Agoraphobic symptoms generally take longer to respond than panic symptoms.

#### The acute encounter
A 14-year-old Hispanic female presents to the pediatric clinic, accompanied by her mother, with complaints of nausea, bloating, and stomach pain. Her mother reports that she is having difficulty adjusting to her new high school and teachers. Mother states “she's always been shy and doesn’t like change, and this time she is having significant difficulty adjusting”. She has missed 4 days of school over the past 3 weeks with complaints of nausea and stomach pain. She is required to participate in a drama production at the school next week and she is refusing.

Her medical history is positive for ADHD

**Meds:** methylphenidate ER (24 hour) 36 mg/day

Her medical workup is noncontributory, and she is diagnosed with SAD

**What treatment options should be considered for AD?**

**What are the benefits of using pharmacotherapy versus psychotherapy versus both?**
**Nonpharmacologic Therapy**

- Patients with PD should avoid stimulant agents (eg, decongestants, diet pills, and caffeine) that may precipitate a panic attack. CBT generally includes psychoeducation, self-monitoring, countering anxious beliefs, exposure to fear cues, and modification of anxiety-maintaining behaviors. Exposure therapy is useful for patients with phobic avoidance. CBT is considered a first-line treatment of PD, with efficacy similar to that of pharmacotherapy. Some studies suggest lower risk of relapse after CBT versus drug therapy. In a trial of PD with or without agoraphobia, SSRI plus CBT was more effective than either therapy alone after 9 months of treatment.

**Pharmacologic Therapy**

- Patients with PD may be treated with TCAs, SSRIs, SNRIs, or MAOIs, as well as benzodiazepines with similar effectiveness, but SSRIs have become the treatment of choice. Benzodiazepines are often used concomitantly with antidepressants, especially early in treatment, or as monotherapy to acutely reduce panic symptoms. Benzodiazepines are not preferred for long-term treatment but may be used when patients fail several antidepressant trials. PD patients with comorbid depression should be treated with an antidepressant. An algorithm for pharmacologic management of PD appears in Figure 40–3.

**Antidepressants**

Antidepressants typically require 4 weeks for onset of antipanic effect, with optimal response at 6 to 12 weeks. Reduction of anticipatory anxiety and phobic avoidance generally follows improvement in panic symptoms. Key Concept PD patients are more likely to experience stimulant-like side effects of antidepressants than patients with major depression. Antidepressants should be initiated at lower doses (see Table 40–6) in PD patients than in depressed patients. Target doses are similar to those used for depression. Key Concept Antidepressants should be tapered when treatment is discontinued to avoid withdrawal symptoms, including irritability, dizziness, headache, and dysphoria.

**Tricyclic Antidepressants** Treatment with imipramine, leaves 45% to 70% of patients panic free. Desipramine and clomipramine are also effective. However, TCAs are considered second- or third-line pharmacotherapy because of poorer tolerability and toxicity on overdose. TCAs are associated with a higher rate of treatment discontinuation than SSRIs. PD patients taking TCAs may experience anticholinergic effects, orthostatic hypotension, sweating, sleep disturbances, dizziness, fatigue, sexual dysfunction, and weight gain. Stimulant-like side effects occur in up to 40% of patients.

**Selective Serotonin Reuptake Inhibitors** SSRIs are the drugs of choice for patients with PD. All SSRIs have demonstrated effectiveness in controlled trials, with 60% to 80% of patients improving in controlled trials. SSRIs/SNRIs are the drugs of choice for patients with PD.

<sup>a</sup> Food and Drug Administration approved for use in panic disorder.

GI, gastrointestinal; MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Data from Refs. 18, 23, and 40.
Social situations almost always provoke fear or anxiety and are avoided or endured with intense fear or anxiety. Children may express fear or anxiety by crying, tantrums, freezing, clinging or failing to speak in social situations. The fear or anxiety is

- out of proportion to the actual threat posed by the social situation;
- persistent, typically lasting for 6 months or more;
- causes clinically significant distress or impairment in social, occupational, or other area of functioning;
- not attributable to physiological effects of a substance or another medical condition; and
- not better explained by the symptoms of another mental disorder (eg, panic disorder, body dysmorphic disorder, or autism spectrum disorder)

### Differential Diagnosis

Rule out underlying medical or psychiatric disorders and medications that may cause anxiety (see Tables 40–1 and 40–2).

### Laboratory Evaluation

Laboratory investigation is of limited value and should be pursued only in context of other history or physical examination findings.

---

**Clinical Presentation and Diagnosis of SAD**

### General

Individuals have marked fear or anxiety about one or more social situations where they are exposed to possible scrutiny or negative evaluation (eg, common social interactions, conversation, eating, drinking or performing). SAD differs from specific phobia, in which the fear and anxiety are limited to a particular object or situation (eg, insects, heights, public transportation). In children, the anxiety must be present in peer settings, not just in interactions with adults.

### Symptoms

- The individual fears acting in a way or showing anxiety that will be negatively evaluated (ie, humiliating or embarrassing or lead to rejection or offend others)
- Social situations almost always provoke fear or anxiety and are avoided or endured with intense fear or anxiety. Children may express fear or anxiety by crying, tantrums, freezing, clinging or failing to speak in social situations.

---

**Serotonin Norepinephrine Reuptake Inhibitors**

Venlafaxine, in dosages of 75 to 225 mg/day, reduced panic and anticipatory anxiety in short-term controlled trials and prevented relapse with extended treatment over 6 months. The most common side effects include headaches, irritability, nausea and other gastrointestinal complaints, insomnia, sexual dysfunction, increased anxiety, drowsiness, and tremor.

**Monoamine Oxidase Inhibitors**

MAOIs have not been evaluated systematically for treatment of PD under the current diagnostic classification and generally are reserved for patients who are refractory to other treatments. They have significant side effects that limit adherence. Additionally, patients must adhere to dietary restriction of tyramine and avoid sympathomimetic drugs to avoid hypertensive crisis (see Chapter 38).

The reversible inhibitors of monoamine oxidase (RIMAs) (brofaromine and moclobemide, [unavailable in the United States]) have been studied with mixed results.

### Other Antidepressants

There is insufficient evidence to support the use of bupropion, trazodone, nefazodone, or mirtazapine for treatment of PD.

**Benzodiazepines**

Benzodiazepines are effective antipanic agents with significant effects on anticipatory anxiety and phobic behaviors. Alprazolam, the benzodiazepine most studied, is associated with significant panic reduction after 1 week of therapy (eg, 55%-75% panic free). Benzodiazepines achieve outcomes similar to antidepressants over extended treatment, but benzodiazepine-treated patients...
are more likely to relapse when the drugs are discontinued.\textsuperscript{42} The risk for dependence and withdrawal and lack of efficacy for depression are significant concerns for long-term treatment of patients with PD. There is no evidence that tolerance to therapeutic effect occurs. Patients with PD experience greater rebound anxiety and relapse when discontinuing benzodiazepines than do patients with GAD. Tapering should be done at a slower rate and over a more extended period of time than with other anxiety disorders.\textsuperscript{18,42}

\begin{keyconcept}
The dose of benzodiazepine required for improvement generally is higher than that used in other anxiety disorders, and this may explain why high-potency agents such as alprazolam and clonazepam generally are preferred. Lorazepam and diazepam, when given in equivalent doses, produce similar treatment benefits.\textsuperscript{18,42} Doses should be titrated to response (see Table 40–4). The use of extended-release alprazolam or clonazepam may minimize breakthrough panic symptoms that are sometimes observed with immediate-release alprazolam.\textsuperscript{45}

The most common side effects of benzodiazepines are sedation, fatigue, and cognitive impairment.\textsuperscript{42} Benzodiazepines should be avoided in patients with current or past substance abuse or dependence or sleep apnea. Additionally, caution should be used in older adults because they have more pronounced psychomotor and cognitive side effects.
\end{keyconcept}

\begin{itemize}
\item \textbf{β-Blockers}
\end{itemize}

Pindolol 25 mg three times a day is an effective adjunctive treatment with an SSRI.\textsuperscript{45} Propranolol 120 to 240 mg/day has been found equivalent to alprazolam in reduction of panic attacks.\textsuperscript{42} β-blockers are not expected to reduce psychic anxiety or avoidance behavior. Additionally, heart rate and blood pressure reduction are dose-related adverse events that may limit use.

\begin{keyconcept}
\begin{itemize}
\item SSRIs are considered the drugs of choice based on their tolerability and efficacy for SAD and comorbid depression if present.
\item The onset of response for antidepressants may be as long as 8 to 12 weeks.\textsuperscript{18,47}
\item Patients responding to medication should be continued on treatment for at least 1 year. Many patients relapse when medication is discontinued, and there are no clear predictive factors for who will maintain response.\textsuperscript{47} Some patients may elect more long-term treatment owing to fear of relapse. A suggested treatment algorithm is shown in Figure 40–4.
\end{itemize}
\end{keyconcept}

\begin{itemize}
\item \textbf{Selective Serotonin Reuptake Inhibitors and Venlafaxine}
\end{itemize}

The efficacy of paroxetine, sertraline, escitalopram, fluvoxamine, and venlafaxine was established in large controlled trials.\textsuperscript{18,47,48} SSRIs and SNRIs improve social anxiety and phobic avoidance and reduce overall disability. Approximately 50% of patients achieve response during acute treatment. Limited data support the effectiveness of citalopram and fluoxetine in SAD.\textsuperscript{47,49}

The initial dose of SSRI is similar to that used in depression. Patients should be titrated as tolerated to response. Many patients require maximum recommended daily doses. Patients with comorbid PD should be started on lower doses (see Table 40–6). When discontinuing SSRIs, the dose should be tapered slowly to avoid withdrawal symptoms. Relapse rates may be as high as 50%, and patients should be monitored closely for several weeks.\textsuperscript{46,47} Side effects of SSRIs in SAD are similar to those seen in depression and include nausea, sexual dysfunction, somnolence, and sweating.

Venlafaxine extended release, in doses of 75 to 225 mg/day, has similar efficacy to SSRIs.\textsuperscript{18} Doses should be tapered slowly when discontinuing. Common side effects are anorexia, dry mouth, nausea, insomnia, and sexual dysfunction.

\begin{itemize}
\item \textbf{Monoamine Oxidase Inhibitors and Reversible Inhibitors of Monoamine Oxidase}
\end{itemize}

Phenelzine, effective in 64% to 69% of SAD patients,\textsuperscript{57} is generally reserved for treatment-refractory patients owing to dietary restrictions,\textsuperscript{49} drug interactions, and side effects. The RIMAs brofaromine and meclobemide are also effective.
Social Anxiety Disorder

Comorbid depression, anxiety disorder, or substance abuse

SSRI or venlafaxine XR

Response: Continue for 12 months

No response: Switch to another SSRI or venlafaxine XR

Partial response: Augmentation with buspirone

Urgency to treat, no history of substance abuse

BZ + SSRI or venlafaxine XR

Inadequate response: Switch to phenelzine

Inadequate response: Pregabalin or gabapentin

Response: Continue for 12 months

Patient Care Process

Patient Assessment:
- Based on clinical presentation and mental status exam, determine whether the patient is experiencing symptoms of sufficient intensity and duration to warrant treatment. Is there functional impairment?
- Based on physical exam and review of systems, does the patient have another condition causing anxiety?
- Determine if the patient has another psychiatric condition, such as depression or a substance use disorder? Is the patient experiencing suicidal ideation?
- Conduct a medication history (including prescriptions, over-the-counter (OTC) medications, and dietary supplements) to identify possible causes of anxiety/panic. Does the patient have any drug allergies? Is the patient experiencing side effects from therapy?

Therapy Evaluation:
- Determine whether treatment for the anxiety disorder is needed and if pharmacotherapy is preferred over behavioral interventions based on symptom severity and previous treatment and response.

Care Plan Development:
- If patient is already receiving pharmacotherapy, assess efficacy, safety, and patient adherence. Are there any significant drug interactions?

Follow-up Evaluation:
- Select lifestyle modifications and antianxiety therapy that are likely to be effective and safe. Used shared decision making for selection of behavioral and pharmacotherapy intervention(s). Consider comorbid conditions when selecting initial agent.
- Address any patient concerns about anxiety and its management.
- Discuss importance of medication adherence and lifestyle modifications.

Follow-up at monthly intervals or more frequently during acute treatment to assess effectiveness and tolerability.
- Use appropriate rating scales to assess symptom change over time.
- Once anxiety is controlled and baseline function restored, determine the appropriateness of treatment beyond 1 year based on the patient’s previous treatment, comorbidities, and ongoing environmental stressors.
### Alternative Agents

**Benzodiazepines** Benzodiazepines are used commonly in SAD; however, limited data support their use. Clonazepam was shown effective for social anxiety, fear, and phobic avoidance, and it reduced social and work disability during acute treatment. Long-term treatment is not desirable for many SAD patients because of the risk of withdrawal and difficulty with discontinuation, cognitive side effects, and lack of effect on depressive symptoms. Benzodiazepines may be useful for acute relief of physiologic symptoms of anxiety when used concomitantly with antidepressants or psychotherapy. Benzodiazepines are contraindicated in SAD patients with current or past alcohol or substance abuse.

**Anticonvulsants** Gabapentin and pregabalin, structurally similar anticonvulsants, have each demonstrated modest benefit in a randomized, placebo controlled trial. Gabapentin was titrated to a maximum dose of 3600 mg/day and pregabalin to 600 mg/day. While both medications have good tolerability, they should be considered for patients with inadequate response to SSRI/SNRIs.

**β-Blockers** β-blockers decrease the physiologic symptoms of anxiety and are useful for reducing performance anxiety. Propranolol or atenolol should be administered 1 hour before a performance situation. β-blockers are not useful in SAD.

### Outcome Evaluation

**Key Concept** Pharmacotherapy for patients with SAD should lead to improvement in anxiety and fear, functionality, and overall well-being. Many patients will experience significant improvement in symptoms but may not achieve full remission. Monitor patients weekly during acute treatment (eg, initiation and titration of pharmacotherapy) and monthly once stabilized. Inquire about adverse effects, SAD symptoms, suicidal ideation, and symptoms of comorbid psychiatric conditions at each visit. Ask patients to keep a diary to record fears, anxiety levels, and behaviors in social situations. Administer the Leibowitz Social Anxiety Scale (LSAS) to rate SAD severity and change, and the Social Phobia Inventory can be used as a “self-assessment” tool. Counsel patients on appropriate expectations of pharmacotherapy in SAD, including gradual onset of effect and the need for extended treatment of at least 6 months following response.

### Abbreviations Introduced in This Chapter

- CBT: Cognitive-behavioral therapy
- CNS: Central nervous system
- DA: Dopamine
- FDA: Food and Drug Administration
- GABA: γ-aminobutyric acid
- GAD: Generalized anxiety disorder
- HPA: Hypothalamic-pituitary-adrenal
- 5-HT: Serotonin
- LC: Locus ceruleus
- LSAS: Liebowitz Social Anxiety Scale
- MAOI: Monoamine oxidase inhibitor
- MDD: Major depressive disorder
- NCS-R: National Comorbidity Survey, Revised
- NE: Norepinephrine
- NPY: Neuropeptide Y
- OCD: Obsessive-compulsive disorder
- OTC: Over-the-counter
- PD: Panic disorder
- PDSS: Panic Disorder Symptom Scale
- RAS: Reticular activating system
- RIMA: Reversible inhibitors of monoamine oxidase A
- SAD: Social anxiety disorder
- SGA: Second-generation antipsychotic
- SNRI: Serotonin-norepinephrine reuptake inhibitor
- SSRI: Selective serotonin reuptake inhibitor
- TCA: Tricyclic antidepressant

### REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List the sequelae of undiagnosed or untreated sleep disorders and appreciate the importance of successful treatment of sleep disorders.
2. State the incidence and prevalence of sleep disorders.
3. Describe the pathophysiology and characteristic features of the sleep disorders covered in this chapter, including insomnia, narcolepsy, restless legs syndrome (RLS), obstructive sleep apnea (OSA), and parasomnias.
4. Assess patient sleep complaints, conduct sleep histories, and evaluate sleep studies to recognize daytime and nighttime symptoms and characteristics of common sleep disorders.
5. Recommend and optimize appropriate sleep hygiene and nonpharmacologic therapies for the management and prevention of sleep disorders.
6. Recommend and optimize appropriate pharmacotherapy for sleep disorders.
7. Describe the components of the patient care process to implement and assess safety and efficacy of pharmacotherapy for common sleep disorders.
8. Educate patients about preventive behavior, appropriate lifestyle modifications, and drug therapy required for effective treatment and control of sleep disorders.

INTRODUCTION

Individuals with normal sleep patterns sleep up to one-third of their lives and spend more time sleeping than in any other single activity. Despite this, our understanding of the full purpose of sleep and the mechanisms regulating sleep homeostasis remains incomplete. Sleep is necessary to enable one to maintain wakefulness and good health. Disruption of normal sleep is a major cause of societal morbidity, lost productivity, and reduced quality of life. Sleep disturbances may contribute to the development and progression of comorbid medical conditions.

Sleep is governed and paced by the suprachiasmatic nucleus in the brain that regulates circadian rhythm. Environmental cues and amount of previous sleep also influence sleep on a daily basis. There are two main types of sleep: rapid eye movement (REM) sleep, during which eye movements and dreaming occur but the body is mostly paralyzed, and non–rapid eye movement (NREM) sleep, which consists of four substages (stages 1–4). Stage 1 serves as a transition between wake and sleep. Most of the time asleep is spent in stage 2 NREM sleep. Stages 3 and 4 sleep often are grouped together and referred to as deep sleep, or delta sleep, because prominent delta waves are seen on the electroencephalogram (EEG) during these sleep stages.

EPIDEMIOLOGY AND ETIOLOGY

Approximately 50% of adults will report a sleep complaint over the course of their lives. In general, sleep disturbances increase with age, and each disorder may have gender differences. The full extent and impact of disordered sleep on our society are not known because many patients’ sleep disorders remain undiagnosed. Normal sleep, by definition, is “a reversible behavioral state of perceptual disengagement from and unresponsiveness to the environment.” Individuals with sleep disorders exhibit or complain about consequent symptoms (eg, daytime sleepiness) or a bed partner often observes hallmark characteristics of the sleep disorder. Insomnia, RLS, and sleep-related breathing disorders are the most common sleep disorders.

Insomnia

The prevalence of insomnia increases with age and is nearly 1.5 times greater in women than in men. Approximately one-third of patients older than age 65 years have persistent insomnia. About 10% of adults experience chronic insomnia, and slightly more experience short-term insomnia. Insomnia is most frequently a symptom or manifestation of an underlying disorder (comorbid or secondary insomnia) but may occur in the absence of contributing factors (primary insomnia). Forty percent of patients with psychiatric conditions have accompanying insomnia. Secondary insomnia
may be triggered by acute stress and resolve when the stress resolves. Numerous coexisting medical conditions, such as pain, thyroid abnormalities, asthma, and gastroesophageal reflux, and medications, including selective serotonin reuptake inhibitors (SSRIs), steroids, stimulants, and β-agonists, can cause insomnia.

**Narcolepsy**

Although difficult to estimate, the prevalence of narcolepsy is between 0.03% and 0.06%. Signiﬁcant differences have been reported for various ethnic groups. Narcolepsy has a higher prevalence in a Japanese and a lower prevalence in Israeli populations. Cataplexy is not required for diagnosis; however, between 50% and 80% of patients with narcolepsy have accompanying cataplexy.

**Restless Legs Syndrome**

RLS occurs in 6% to 12% of the population. Prevalence increases with age and in various medical conditions, such as end-stage renal disease, pregnancy, and iron deﬁciency. RLS appears to be more common in women than in men and has a genetic link in a majority of patients.

**Obstructive Sleep Apnea**

OSA affects 4% of middle-aged white men and 2% of middle-aged white women. In women, the frequency increases after menopause. Prevalence is the same or higher in African Americans and lower in Asian populations. The risk for OSA increases with age and obesity. Individuals with OSA experience repetitive upper airway collapse during sleep, which decreases or stops airflow, with subsequent arousal from sleep to resume breathing. Severity is determined by nocturnal polysonomography (NPSG) or home sleep study and is graded by the number of episodes of apnea (total cessation of airflow) and hypopnea (partial airflow closure with blood oxygen desaturation) experienced during sleep. Severity is expressed as the respiratory disturbance index (RDI), quantified in events per hour.

**Parasomnias**

NREM parasomnias have variable prevalence rates depending on patient age and comorbid diagnoses. Sleep talking, bruxism, sleepwalking, sleep terrors, and enuresis occur more frequently in childhood than in adulthood. Nightmares appear to occur with similar frequency in adults and children. REM-sleep behavior disorder (RBD), an REM-sleep parasomnia, has a reported prevalence of 0.5%, is more common in elderly men, and frequently is associated with concomitant neurologic conditions.

**PATHOPHYSIOLOGY**

Although the neurophysiology of sleep is complex, certain neurotransmitters promote sleep and wakefulness in different areas of the central nervous system (CNS). Whereas serotonin is thought to control NREM sleep, cholinergic and adrenergic transmitters mediate REM sleep. Dopamine, norepinephrine, hypocretin, substance P, and histamine all play a role in wakefulness. Perturbations of various neurotransmitters are responsible for some sleep disorders and explain why various treatments are beneficial.

**Insomnia**

There is no single pathophysiologic explanation for the manifestations of insomnia. Current hypotheses focus on a combination of possible models that incorporate physiologic, cognitive, and cortical arousal. Most models focus on hyperarousal and its interference with the initiation or maintenance of sleep.

**Narcolepsy**

The onset of narcolepsy–cataplexy is typically in adolescence, suggesting that the disease may require environmental influence to develop. Currently, it is believed that narcolepsy results from autoimmune insult to the CNS because it is associated with human leukocyte antigen (major histocompatibility complex) DQB10602 and DQA1*0102. Concentrations of hypocretin (a wake-promoting neuropeptide) in the cerebrospinal fluid of patients with narcolepsy are reduced significantly, suggesting that the autoimmune attack is against hypocretin-producing cells in the hypothalamus.

**Restless Legs Syndrome and Periodic Limb Movements of Sleep**

RLS is a neurologic medical condition characterized by an irresistible desire to move the limbs. It is thought that these abnormal sensations are a result of iron deﬁciency in the brain and iron-handling abnormalities in the CNS. Iron and H-ferritin concentrations, along with transferrin receptor and iron transporter numbers, are reduced in the substantia nigra of patients with RLS. These iron abnormalities lead to dysfunction of dopaminergic transmission in the substantia nigra. Recently, it has been suggested that local hypoxia in the legs may contribute to pathophysiology of RLS.

**Obstructive Sleep Apnea**

At least 20 muscles and soft tissue structures control patency of the upper airway. Patients with OSA may have differences in upper airway muscle activity during sleep and may have smaller airways, predisposing them to upper airway collapse and consequent apneic episodes during sleep. The inability of the upper airway to contend with factors that promote collapse, including fat deposition in the neck, negative pressure in the airway during inspiration, and a smaller jawbone, also may play a role in the pathogenesis of OSA.

Poor sleep architecture and fragmented sleep secondary to OSA can cause excessive daytime sleepiness (EDS) and neurocognitive deﬁcits. These sequelae can affect quality of life and work performance and may be linked to occupational and motor vehicle accidents. OSA is also associated with systemic disease such as hypertension, heart failure, and stroke. OSA is likely an independent risk factor for the development of hypertension. Furthermore, when hypertension is present, it is often resistant to antihypertensive therapy. Patients with sleep apnea often are obese and may be predisposed to weight gain. Hence, obesity may further contribute to cardiovascular disease in this patient population.

Several factors suggest an association between OSA and systemic disease. Breathing against a closed upper airway during sleep causes intermittent and repetitive episodes of hypoxemia and hypercapnia, dramatic changes in intrathoracic pressure, and activation of the sympathetic nervous system. These responses can produce acute hemodynamic and humoral responses. Blood pressure can increase to 220/120 mm Hg with each apneic episode.

**Parasomnias**

The pathogenesis of parasomnias (eg, sleepwalking, enuresis, sleep talking) is variable poorly described, and involves state dissociation, whereby two states of being overlap simultaneously. For example, abnormal activation of the central pattern generator of the spinal cord that produces motor movements is hypothesized to underlie sleepwalking behavior. In RBD, active...
Sleep paralysis or hallucinations when waking or falling asleep. Cataplexy

Cessation of breathing (apnea), snoring

Inability to fall asleep, nighttime awakenings

Sleep walking (somnambulism), sleep talking (somniloquy)

Confusion or impaired performance at work or school

Hypertension

Restlessness (PLMS or RLS)

inhibition of motor activity in the perlocus coeruleus region is lost, resulting in loss of paralysis and dream enactment.

**CLINICAL PRESENTATION AND DIAGNOSIS**

KEY CONCEPT Although the clinical history guides diagnosis and therapy, only NPSG, home sleep studies, and/or multiple sleep latency tests (MSLTs) can definitively diagnose and guide therapy for OSA, narcolepsy, and periodic limb movements of sleep (PLMS). All patients presenting with sleep complaints should have a thorough interview and history to inventory their sleep habits and sleep hygiene.

**Insomnia**

Insomnia is often characterized by difficulty falling asleep, frequent nocturnal awakenings, early morning awakenings, and nonrestorative sleep, which may result in daytime impairments in concentration and school or work performance. In comorbid (secondary) insomnia, social factors (eg, family difficulties, bereavement), medications (eg, antidepressants, β-agonists, corticosteroids, decongestants), and coexisting medical or psychiatric conditions (eg, depression, bipolar disorder) may help to explain difficulties in initiating and maintaining sleep. Insomnia duration may be described as transient (less than 1 week), acute (1–4 weeks), or chronic (greater than 1 month) in duration.

**Narcolepsy**

The hallmark of narcolepsy is EDS and the need for periods of sleep during the day. Patients with narcolepsy may experience repeated nighttime awakenings, terrifying dreams, and difficulty falling asleep. They frequently experience abnormal manifestations of REM sleep, including hallucinations and sleep paralysis that occur on falling asleep and/or awakening. Cataplexy is a weakness or loss of skeletal muscle tone in the jaw, legs, or arms that is elicited by emotion (eg, anger, surprise, laughter, or sadness).

**Obstructive Sleep Apnea**

Common characteristics of OSA include snoring, choking, gasping for air, nocturnal reflux symptoms, and morning headaches. A bed partner or roommate may observe these symptoms and witness apneic episodes where the patient stops breathing. Patients with large neck sizes (greater than 45 cm (~18 in) neck circumference) and a body mass index (BMI) of 30 kg/m² or greater are at higher risk for OSA.

**Periodic Limb Movements of Sleep and Restless Legs Syndrome**

Although RLS symptoms can vary, patients commonly report creepy-crawly, burning, tingling, or achy feelings in the legs or arms. These sensations create a desire to move the limbs and may produce motor restlessness. Symptoms are worse in the evening and are worse or exclusively present at rest, with temporary relief with movement. Symptoms also can occur during sleep and often lead to semirhythmic PLMS. PLMS are objective findings during NPSG recorded by leg electrodes. PLMS are present in most patients with RLS but can occur independently.

**Parasomnias**

Parasomnias are characterized by undesirable physical or behavioral phenomena that occur during sleep (eg, sleepwalking, sleep eating, sleep talking, bruxism [grinding of teeth], enuresis, night terrors, and RBD). People with RBD act out their dreams during sleep, often in a violent manner.

**Circadian Rhythm Disorders**

The most common circadian rhythm disorders (CRDs) include jet lag, shift-work sleep disruption, delayed sleep-phase disorder, and advanced sleep-phase disorder. Jet lag occurs when a person travels across time zones, and the external environmental time is mismatched with the internal circadian clock. Delayed and advanced sleep-phase disorders occur when bed and wake times are delayed or advanced (by 3 or more hours) compared with socially prescribed bed and wake times.

**Sleep Diagnostics**

Complete NPSG is the “gold standard” for diagnosing and identifying sleep-disordered breathing, PLMS, parasomnias, and nocturnal sleep irregularities related to narcolepsy. Sleep is observed and monitored in a controlled setting using an EEG, electrooculography, electromyography, electrocardiography, air thermistors, abdominal and thoracic strain belts, and an oxygen saturation monitor. This setup records sleep onset, arousals, sleep stages, eye movements, leg and jaw movements, heart rhythm, airflow, respiratory effort, and oxygen desaturations. Home sleep studies are increasingly used to diagnose sleep apnea due to their reduced cost and increased patient convenience. These devices typically measure nasal air flow, respiratory effort, oxygen saturation, and heart rate to determine if a patient experiences apnea/hypopnea episodes.

The MSLT is a commonly performed test to assess daytime sleepiness. During the MSLT, the patient attempts to take a 20-minute nap every 2 hours during the day beginning 2 hours...
after morning awakening (after a normal night’s sleep) to evaluate physiologic sleepiness. The patient is instructed not to resist the urge to fall asleep. Sleep latency of less than 5 or 6 minutes is considered pathologically sleepy. The occurrence of an REM onset period during two naps with short sleep latency is indicative of a diagnosis of narcolepsy.

TREATMENT

Desired Outcomes

**KEY CONCEPT** Treatment goals vary among different sleep disorders but generally include restoration of normal sleep patterns, elimination of daytime sequelae, improved quality of life, and prevention of complications and adverse effects from therapy.

General Approach to Treatment

- Nonpharmacologic interventions for insomnia are outlined in Table 41–1. Sleep hygiene should be reinforced in all patients, and behavioral, cognitive, and stimulus-control interventions are used mainly for patients with insomnia-type complaints. Both pharmacologic and nonpharmacologic therapies are effective at improving sleep and reducing insomnia complaints. An algorithm for the initial assessment and first treatment step of EDS is provided in Figure 41–1.

Insomnia

**KEY CONCEPT** Early treatment of insomnia may prevent the development of persistent psychophysiological insomnia. The ideal hypnotic drug would be effective at reducing sleep latency, increasing total sleep time, and would be free of unwanted side effects.

**KEY CONCEPT** Benzodiazepine receptor agonists (BZDRAs) (including traditional benzodiazepines, zolpidem, zaleplon, and eszopiclone) and ramelteon are approved by the Food and Drug Administration (FDA) for the treatment of insomnia and are first-line therapies.

Pharmacokinetic differences between the eight BZDRAs help to guide selection, depending on patient considerations and specific sleep complaints (Table 41–2). These agents occupy the benzodiazepine site on the γ-aminobutyric acid (GABA) type A receptor complex, resulting in opening of chloride channels that facilitate GABA inhibition and promote sleepiness.

BZDRAs have become the first-line agents for treating insomnia and sleep-maintenance problems. They are all efficacious, have wide therapeutic indices, and have a low incidence of abuse.

Patients should be instructed to take BZDRAs at bedtime and avoid activities requiring alertness after ingestion. Although BZDRAs generally are well tolerated and have good safety profiles, mild to moderate side effects can occur, and precautions are warranted.

**Precautions and Safety** The most common side effects associated with BZDRAs include residual sedation into the waking hours after sleep, grogginess, and psychomotor impairment.

Selection of a hypnotic with a duration of action matching the patient’s budgeted sleep time can help minimize the risk of residual sedation. BZDRAs should be initiated at low doses, and agents with active metabolites (see Table 41–2) should be avoided in elderly patients. BZDRAs may cause anterograde amnesia, defined as memory loss of activities and interactions after ingestion of the drug. All sedatives can cause anterograde amnesia, and higher doses increase the extent of amnesia.

On discontinuation of hypnotic BZDRAs, patients may experience rebound insomnia that may last for a few nights. Rebound insomnia occurs more frequently after discontinuation of shorter duration BZDRAs compared with longer duration BZDRAs. Intermittent hypnotic therapy with the lowest dose possible reduces the likelihood of tolerance, dependence, and withdrawal when therapy is stopped. Patients should be counseled that rebound insomnia is not necessarily a return of their original symptoms, and it may take a few nights for rebound symptoms to subside. In general, eszopiclone, zaleplon, and zolpidem appear to be associated with lower risk of tolerance, rebound insomnia, and withdrawal than traditional benzodiazepines.

**Sedating Antidepressants**

Sedating antidepressants (eg, trazodone, amitriptyline, mirtazapine, nefazodone, doxepin) are commonly used for insomnia and may be an appealing option in patients with concomitant depression. However, at the doses frequently used for sleep, only mirtazapine exhibits significant antidepressant activity. Furthermore, quality clinical studies demonstrating efficacy for insomnia are lacking. Side effects from antidepressants can be frequent, including carryover sedation, grogginess, anticholinergic effects, and weight gain. Tricyclic antidepressants (TCAs) should be used with caution in the elderly and patients with cardiovascular and hepatic impairment. Mirtazapine can cause daytime sedation, dizziness, and weight gain, and trazodone can
Excessive Daytime Sleepiness

Clinical History

- Symptoms strongly suggest RLS
- Symptoms suggest narcolepsy

Empiric therapy with DA

• Ensure DA at moderate dose
• Switch to gabapentin, opioid, or hypnotic BZDRA
• Add gabapentin or hypnotic BZDRA

Inadequate response or side effect?

- If yes

- NPSG and MSLT

Positive for narcolepsy?

If yes

- Modafinil, methylphenidate, or amphetamines

Cataplexy or REM sleep abnormalities?

If yes

- SNRI, TCA, or sodium oxybate

History indicates difficulty initiating or maintaining sleep

• Evaluate for possible contribution of current medications
• May consider NPSG if suspect other sleep disorders
• Educate about sleep hygiene
• Nonpharmacologic therapy if appropriate
• Treat concomitant and underlying conditions
• BZDRA therapy or ramelteon

Sleepiness persists?

If yes

• Titrate dose of BZDRA as necessary
• Switch drugs if troublesome side effect or if not effective
• Reinforce sleep hygiene

Symptoms suggest OSA

NPSG or home sleep study

If OSA present, CPAP therapy

Ensure adequate CPAP use and modafinil or armodafinil for residual sleepiness

FIGURE 41–1. Primary assessment and initial treatment for complaint of excessive daytime sleepiness. BZDRA, benzodiazepine receptor agonist; CPAP, continuous positive airway pressure; DA, dopamine agonist; MSLT, multiple sleep latency test; OSA, obstructive sleep apnea; RLS, restless legs syndrome; SNRI, serotonin and norepinephrine reuptake inhibitor; NPSG, nocturnal polysomnography; TCA, tricyclic antidepressant.

cause hypotension and dizziness and should be used with caution in patients with heart disease or hypertension and those taking cardiovascular agents.33,34 Doxepin is approved for treatment of sleep maintenance insomnia in low doses (3–6 mg).

> Over-the-Counter and Other Miscellaneous Agents

Over-the-counter antihistamines such as diphenhydramine are frequently used (usual doses, 25–50 mg) for difficulty sleeping. Diphenhydramine is approved by the FDA for the treatment of insomnia and can be effective at reducing sleep latency and increasing sleep time.35 However, diphenhydramine produces undesirable anticholinergic effects and carryover sedation that limit its use, especially in the elderly. Valerian root is an herb that has inconsistent effects on sleep but may reduce sleep latency and increase efficiency at commonly used doses of 400 to 900 mg valerian extract. Ramelteon, a melatonin receptor agonist, is indicated for insomnia characterized by difficulty with sleep onset. Ramelteon is not a controlled substance and can be a viable option for patients with a history of substance abuse. It has documented efficacy treating sleep onset difficulties in those with mild to moderate chronic obstructive pulmonary disease and OSA.36–38 Suvorexant (an orexin receptor antagonist) was recently approved for treatment of insomnia. It is the first medication that turns off wakefulness mechanisms instead of stimulating pathways that induce sleepiness. Suvorexant is indicated for both difficulty initiating and maintaining sleep, and like BZDRAs, it is classified as a schedule IV controlled substance.39

Narcolepsy

Therapy for narcolepsy involves two key principles: (a) treatment of EDS with scheduled naps and CNS stimulants and (b) suppression of cataplexy and REM-sleep abnormalities with aminergic signaling.

Patient Encounter, Part 1

An 18-year-old woman with a history of asthma comes to your clinic complaining of excessive daytime sleepiness, disrupted nighttime sleep, and strange weakness when she is surprised. She reports that she falls asleep relatively easily during the day if given a chance. She takes ethinyl estradiol/norethindrone 35 mcg/1 mg, albuterol MDI two puffs as needed shortness of breath, and fluticasone MDI 100 mcg two puffs twice a day.

What sleep disorders do her symptoms suggest?

What additional information do you need to know in your assessment of this patient?

$^a$In 2007, the Food and Drug Administration required additional information added to the safety labeling of sedative–hypnotic drugs concerning potential risks, including severe allergic reactions and complex sleep-related behaviors, which may include sleep driving. Sleep driving is defined as driving while not fully awake after ingestion of a sedative–hypnotic product with no memory of the event.

$^b$If a dosing range is displayed, the first dose listed should be the starting dose.

$^c$Data not available.

$^d$For zolpidem, recommended dose for women is 5 mg, 6.25 mg for zolpidem CR, and 1.75 mg for sublingual zolpidem.

Drugs. Modafinil (Provigil), armodafinil (Nuvigil), methylphenidate, and amphetamines are effective FDA-approved drugs for the treatment of EDS with narcolepsy. Modafinil and armodafinil (the active R-isomer of modafinil) are Schedule IV medications, and these drugs may have fewer peripheral and cardiovascular effects than traditional stimulants. Selegiline, a selective monoamine oxidase B enzyme inhibitor, is metabolized to amphetamines and can reduce daytime sleepiness. In an individual patient, one wake-promoting agent may work better than another, and if the first drug selected is not successful at adequate doses, a trial with another agent should be attempted. **KEY CONCEPT** Treatment of EDS in narcolepsy and other sleep disorders may require sustained- and immediate-release stimulants to promote wakefulness throughout the day and at key times that require alertness. One potential treatment regimen includes a sustained-release stimulant preparation first thing in the morning and again at noon followed by an immediate-release stimulant preparation as needed in the late afternoon or before driving to maintain wakefulness. One advantage of traditional CNS stimulants over modafinil is their ability to help control cataplexy and REM-sleep abnormalities.

Traditional CNS stimulants have the potential to increase blood pressure and heart rate when used long term. In addition, excessive CNS stimulation can cause tremors and tics and can carry over into evening hours, disrupting normal nighttime sleep. Caution should be used in patients with underlying cardiovascular or cerebrovascular disease and in patients with a history of seizures because stimulants may lower the seizure threshold.

**Cataplexy**

Traditionally, aminergic signaling antidepressants have been used effectively to control symptoms of cataplexy, sleep paralysis, and other REM-sleep manifestations of narcolepsy. These include TCAs and certain selective serotonin and serotonin/norepinephrine reuptake inhibitors (SSRIs and SNRIs). Clomipramine, protriptyline, imipramine, venlafaxine, and fluoxetine are the agents that have been used most frequently. In addition, low-dose selegiline
may be effective at reducing cataplexy. Although not approved by the FDA for treatment of cataplexy, these drugs suppress REM sleep and have been the mainstay of anticataplectic therapy for years. Sodium oxybate, a potent sedative with a very short duration of action, is FDA approved for the treatment of narcolepsy with cataplexy. Its mechanism of action is not entirely known. Two doses per night are taken, one at bedtime and one follow-up dose taken 2½ hours later. Sodium oxybate is tightly regulated and is available from only one central pharmacy because of its high abuse potential.

Restless Legs Syndrome

**Key Concept**

RLS treatment involves suppression of abnormal sensations and leg movements and consolidation of sleep. Dopaminergic and sedative–hypnotic medications are prescribed commonly. Dopamine agonists (DAs) successfully treat RLS symptoms and offer many advantages over levodopa–carbidopa, including longer half-lives to cover overnight symptoms, flexible dosing, and a reduced incidence of symptom augmentation. Up to 80% of patients who take levodopa–carbidopa eventually will experience symptom augmentation: RLS symptoms appear earlier in the day, previously unaffected body parts become involved, duration of relief gets shorter, and higher doses of medication are required to control symptoms. Augmentation may be reduced by use of longer-duration DAs. Ropinirole (Requip), pramipexole (Mirapex), and rotigotine (Neupro) are FDA approved for the treatment of RLS and are available in sustained-release products. Gabapentin is an effective treatment for RLS, particularly in patients with painful symptoms. The gabapentin produrg (gabapentin enacarbil) is FDA approved for RLS at a recommended dose of 600 mg taken with food at about 5 pm. BZDRAs such as temazepam, clonazepam, zolpidem, and zaleplon reduce arousals in patients with RLS. Their main benefit is derived from improving sleep continuity in patients with RLS, particularly as adjunct treatment with other pharmacologic therapies. Opioids are effective in some patients with RLS symptoms, with oxycodeone, hydrocodone, and codeine being used most frequently. For both BZDRAs and opioids, caution should be used in the elderly, in patients who are at risk for sleep apnea, and in patients with a history of substance abuse. Low iron levels frequently exacerbate RLS symptoms. Iron supplementation should be prescribed in patients who are iron deficient. Iron supplementation in patients with serum ferritin concentrations of less than 50 to 75 mcg/L (ng/mL; 112–169 pmol/L) improves RLS symptoms. Medications frequently used for RLS are shown in Table 41–3.

Obstructive Sleep Apnea

**Key Concept**

The main therapy for OSA is nasal continuous positive airway pressure (CPAP) therapy, which alleviates sleep-disordered breathing by producing a positive pressure column in the upper airway using room air. A flexible tube connects the CPAP machine to a mask that covers the nose. CPAP therapy has a favorable impact on blood pressure and attenuates some of the potential hemodynamic and neurohumoral responses that may link OSA to systemic disease.

Not all individuals tolerate CPAP therapy, in part because it requires wearing a mask during sleep, and therapy can dry and irritate the upper airway. In some individuals, these barriers for adherence may be lessened or eliminated by properly fitting the mask, adding humidity to therapy, or using bilevel positive airway pressure (BiPAP) or auto titrating continuous positive airway pressure (AutoPAP) therapy. BiPAP therapy applies a variable pressure into the airway during the inspiratory phase of respiration but, unlike CPAP, reduces the applied pressure during the expiratory phase. AutoPAP machines are set for a pressure range and individualizes the pressure based on breath-to-breath analysis of the necessary pressure to keep the airway open.

Obesity can worsen sleep apnea, and weight management should be implemented for all overweight patients with OSA. In obese patients with mild OSA, weight loss alone can be effective, and studies have reported reduced severity of OSA with gastric stapling. For patients who cannot tolerate CPAP, oral appliances can be used to advance the lower jawbone and to keep the tongue forward to enlarge the upper airway. For individuals who have OSA only when on their backs during sleep, positional therapies may be effective. Surgical therapy (uvulopalatopharyngoplasty) is not a first-line option because of its invasiveness and relatively low long-term effectiveness.

There is no drug therapy for OSA. Drug therapy for symptoms of OSA may be considered in selected patients. Modafinil and armodafinil are wake-promoting medications that are approved by the FDA to treat residual daytime sleepiness despite CPAP therapy. Initiation of these medications should be attempted only after patients are using optimal CPAP therapy to alleviate...

*Usual range; all medications (other than dopaminergic agents) are dosed at bedtime.

¢Dopaminergic agents are frequently given at bedtime or 2 hours before bedtime or the anticipated onset of RLS symptoms.

*May be longer in patients with renal dysfunction.

¢Compulsive behaviors such as gambling, shopping, sexual behaviors, and eating have been reported in patients taking dopamine agonists.

*May be longer in patients with hepatic dysfunction.

sleep-disordered breathing. The need for treating residual sleepiness in this population is not clear because it may not be related to the OSA and is similar to sleepiness in the general population. OSA should always be considered and evaluated in hypertensive patients who are resistant to therapy.

Parasomnias

NREM parasomnias usually do not require treatment. If needed, low-dose BZDRAs such as clonazepam can be prescribed for bothersome episodes. Clonazepam reduces the amount of sleep time spent in stages 3 and 4 of NREM sleep, when most NREM parasomnias occur. For treating RBD, clonazepam 0.5 to 2 mg at bedtime is the drug of choice, although melatonin 3 to 12 mg at bedtime also may be effective. Patients with RBD also should have dangerous objects removed from the bedroom and environmental accommodations made to reduce the chance of injury from breakthrough episodes.

Circadian Rhythm Disorders

Melatonin, 0.5 to 5 mg taken at appropriate target bedtimes for east or west travel, is the drug of choice for jet lag. Melatonin significantly reduces jet lag and shortens sleep latency in travelers.* Hypnotic agents with relatively short durations of action (3–5 hours) may also be used to sustain sleep during the initial adaptation to the new time zone.

Drug–Disease and Drug–Drug Interactions

It is important to review medication profiles for drugs that may aggravate sleep disorders. Patients should be monitored for adverse drug reactions and potential drug–drug interactions and assessed for treatment adherence. Pharmacotherapy for sleep disorders should be individualized. Often medications can treat several concomitant sleep disorders. Conversely, drug therapy may be effective for one sleep disorder and exacerbate another. For example, antidepressants may alleviate depressive symptoms but exacerbate symptoms of RLS. Medications that

Patient Encounter, Part 3: Modifying the Treatment Plan

The patient returns to the clinic 3 months later. The physician previously diagnosed her with narcolepsy and cataplexy. She received a prescription for methylphenidate 20-mg tablets and was instructed to take one tablet twice daily (7 AM and noon). She reports today that the methylphenidate has made her feel more awake and slightly reduced her cataplexy. She still is somewhat sleepy during the day and has cataplexy more often than she would like. Her Epworth Sleepiness Scale (ESS) score today is 13 out of 24. She would like a medication that lasts longer and provides better control of her cataplexy. Based on the information presented, recommend therapy for the patient.

What narcolepsy medications would you not want to use for this patient?

What medication-related precautions would you want to counsel the patient on?
Perform a detailed history of prescription, nonprescription, and complementary or alternative medication use.

Based on patient nighttime and daytime complaints and bed partner report, determine the suspected sleep problem and its consequences.

Review objective and subjective data regarding sleepiness, nighttime sleep quality, and limb movements, sleep disordered breathing, and parasomnias.

Evaluate concomitant sleep and medical conditions that influence therapy decisions.

Evaluate effectiveness, safety, adherence, and side effects of therapy.

Determine whether the patient has insurance coverage for prescribed medications.

For treatment of insomnia, try to ensure the lowest possible doses are prescribed and used for the shortest time period possible.

If patient complaints are not entirely improved, consider increasing dose or adding a complementary agent.

Ensure sleep hygiene (see Table 41–1) and drug therapy are appropriate for each sleep complaint.

Ensure sleep hygiene (see Table 41–1) and drug therapy are appropriate for each sleep complaint.

For insomnia select medications whose duration of action matches the timing of the difficulty sleeping (eg, difficulty initiating or maintaining sleep).

Evaluate improvement in the specific sleep complaint (eg, how has therapy affected sleep latency or sleep maintenance?).

Monitor daytime sleepiness, sleep diaries, and diaries of sleep events (PLMS, hallucinations, snoring, apneas, etc) and monitor cataplexy and other daytime symptoms to determine if therapy is effective.

Make appropriate changes to therapy to address inadequately controlled symptoms and reported adverse effects.

REFERENCES

Attention-deficit/hyperactivity disorder is characterized by a persistent pattern of inattention and/or hyperactivity-impulsivity. It can have a severe impact on a patient’s ability to function in both academic and social environments. Early diagnosis and appropriate treatment are essential to compensate for areas of deficit.

**Epidemiology and Etiology**

This disorder usually begins by 3 years of age but must occur before 12 years of age to meet current diagnostic criteria. In the United States, ADHD is the most common neurobehavioral disorder that affects children. ADHD has been estimated to occur in 4.3% to 9.5% of school-aged children. ADHD occurs more than twice as often in school-aged boys than girls.

Although ADHD generally is considered a childhood disorder, symptoms can persist into adolescence and adulthood. The prevalence of adult ADHD is estimated to be 2.5%; however, 60% of adults with ADHD have symptoms that manifested in childhood. Furthermore, problems associated with ADHD (e.g., social, marital, academic, career, anxiety, depression, smoking, and substance abuse problems) increase with the transition of patients into adulthood.

**Pathophysiology**

The exact pathologic cause of ADHD has not been identified. ADHD is generally thought of as a disorder of self-regulation or response inhibition. Patients who meet the criteria for ADHD have difficulty maintaining self-control, resisting distractions, and concentrating on ideas. Furthermore, children with ADHD often alternate between inattentiveness to monotonous tasks and overexcitement. Multiple brain studies have failed to elucidate any pathophysiologic basis for ADHD.

**Clinical Presentation and Diagnosis**

ADHD is rarely encountered without comorbid conditions and is often undiagnosed. Between 50% and 60% of patients with ADHD will have one or more comorbidities (e.g., learning disabilities, oppositional defiant, conduct, anxiety, or depressive disorders). It is important to identify and appropriately treat coexisting conditions in patients with ADHD.

According to newer diagnostic and treatment guidelines, all patients 4 to 18 years of age presenting with inattention, hyperactivity, impulsivity, academic, and/or behavioral problems should be evaluated for ADHD. Additional information about behavior in various settings should be gathered from the patient, family, and teachers, or supervisors. The age of onset, frequency, severity, and duration of symptoms should be documented.

The most useful diagnostic criteria for ADHD is the *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* (*DSM-5*). The *DSM-5* defines three presentations of ADHD: (a) predominately inattentive; (b) predominantly hyperactive-impulsive; and (c) combined, in which both inattentive and hyperactive or impulsive symptoms are evident.
electroencephalograms, and continuous performance examinations are investigational and not used clinically for diagnosis. It is recommended that parents and teachers complete a standardized rating scale based on the DSM-5 criteria. These rating scales are not by themselves diagnostic but are diagnostic aids when added to a careful history and interview. Although ADHD is considered a childhood disorder, signs and symptoms persist into adolescence in 40% to 80% of cases and into adulthood in approximately 60% of cases. Adult ADHD is difficult to assess, and diagnosis is always suspect in patients failing to display clear symptoms before 12 years of age. Untreated adults with ADHD have higher rates of psychopathology, substance abuse, social dysfunction, and occupational underachievement than adults without ADHD.

**TREATMENT**

**Desired Outcomes**

The primary therapeutic objectives in ADHD are to improve behavior and increase attention or response inhibition; secondary goals of treatment are to:

- Improve relationships with family, teachers, and peers
- Decrease disruptive behavior in academic and social settings
- Improve academic performance
- Increase independence in activities
- Minimize undesirable adverse effects of therapy

**Clinical Presentation and Diagnosis of ADHD**

**General**

Patients with ADHD can present with inattention, hyperactivity–impulsivity, or both. ADHD is typically encountered with comorbid conditions.

**Symptoms**

- Inattentive type: difficulty paying attention to details in school, work, and social activities; difficulty completing tasks that require a lot of mental effort; easily distracted; forgetful
- Hyperactive–impulsive type: difficulty sitting still, fidgets; has trouble playing quietly and waiting turns; frequently interrupts
- Combined: exhibits both inattention and hyperactivity–impulsivity

**Diagnostic Criteria**

- Must exhibit 6 of 9 symptoms before 12 years of age that persist for at least 6 months
- Symptoms must be present in two or more settings and adversely affect functioning in social situations, school, or work
- Must meet the diagnostic criteria in DSM-5 for ADHD
- Symptoms cannot be better explained by another mental disorder (eg, autism)

**Nonpharmacologic (Behavioral) Therapy**

Behavioral therapy can be useful; however, it is generally not recommended as first-line monotherapy except in preschool-aged children (4–5 years of age). Several studies have demonstrated that treatment with medication alone is superior to behavioral intervention alone in improving attention. However, behavioral therapy in combination with stimulant therapy is better at improving oppositional and aggressive behaviors. Behavioral modification involves training parents, teachers, and caregivers to change the physical and social environment and establish a reward or consequence system. Success of behavioral modifications depends on the cooperation and involvement of the patient’s parents and teachers.

**Pharmacologic Therapy**

The proposed mechanism of ADHD pharmacotherapy is to modulate neurotransmitter function in order to improve academic and social functioning. Pharmacologic therapy can be divided into two categories—stimulants and nonstimulants. Stimulants include methylphenidate, dextmethylphenidate, dextroamphetamine–amphetamine (amphetamine salts), dextroamphetamine, and lisdexamfetamine, and nonstimulant medications include atomoxetine, bupropion, clonidine, and guanfacine.

**Stimulants**

Psychostimulants (eg, methylphenidate and dextroamphetamine with or without amphetamine) are the most effective agents in treating ADHD. Following diagnosis of ADHD, a stimulant medication should be considered first-line therapy in patients 6 years of age or older. In preschool-aged children, methylphenidate can be added to the patient’s treatment if behavioral

**Patient Encounter, Part 1**

The single mother of a rowdy 8-year-old boy comes to your clinic. The mother is upset due to a recent altercation with her grandfather over her son’s behavior. Her grandfather claims her son swears, is careless, violent, and has destructive tendencies such as pulling and flicking the hair and head of other family members, especially his 5-year-old brother. She had been living with her parents in an effort to save money since she has a minimum wage job as a room cleaner for a local motel, but recently she has moved her two sons and herself to their own apartment. During the visit, her son is easily distracted, all over the examination room investigating and getting into everything. He even launches a paper airplane twice during the visit which hits both his mother and you. His performance at school on the few assignments he has completed has consistently been failing. During his physical education class, he frequently pushes and shoves others in order to not have to wait for his turn. On two occasions, he has been sent home from school for unruly behavior.

Which of the patient’s symptoms are suggestive of ADHD?
What other comorbid conditions should the child be evaluated for before starting therapy for ADHD?
What other information do you need to assess for ADHD?
What help or suggestions could you offer to his parents?
modifications can be divided into short-, intermediate-, and extended-acting preparations (see Table 42–1). Initial response to short-acting stimulant formulations (eg, methylphenidate and dextroamphetamine) is seen within 30 minutes and can last for 4 to 6 hours. Thus short-acting stimulant formulations must frequently be dosed at least twice daily, increasing the chance of missed doses and noncompliance. Patients using any stimulant formulation, but especially short-acting formulations, can experience a rebound effect of ADHD symptoms as the stimulant wears off.

Most intermediate-acting stimulants release the medication in a slow, continuous fashion without any early release (except Dexedrine Spansules). The onset of action for this category of stimulants (typically 60–90 minutes) may be inadequate for some patients. Some practitioners prescribe a short-acting stimulant concurrently with an intermediate-acting stimulant to curtail the delay in onset of action of the intermediate-acting stimulant. However, this practice can increase patient copay costs.

To minimize rebound symptoms associated with short-acting formulations and still achieve early stimulant release, extended-acting formulations with rapid onsets have been developed. These formulations have an early release of medication and deliver a delayed release of stimulant in either a pulsed (Adderall XR, Focalin XR, Metadate CD, Quillivant XR and Ritalin LA) or continuous manner (Concerta). Formulations available as capsules contain coated beads that can be opened and sprinkled on semisolid food. Concerta tablets have an immediate-release overcoat and an oral osmotic controlled-release that delivers methylphenidate in an extended manner. Patients should be counseled that the empty tablet shell of Concerta can be seen in the stool.

Two extended-acting stimulants, Daytrana and Vyvanse, have a rapid release. Daytrana transdermal patches are to be applied for only 9 hours per day and have a delayed onset of 2 hours, and their effects persist for 3 hours after being removed. Some patients report skin sensitization and irritation. Vyvanse is a prodrug that is hydrolyzed to its active form, dextroamphetamine, after oral ingestion. Inhalation or injection abuse potential is minimized because of impeded hydrolysis by these routes. Onset of action for Vyvanse has been reported to be 2 hours.

Adverse effects of stimulants can be generalized to the whole class (Table 42–1). Most side effects can be managed by changing the dosing routine (ie, giving with food, dividing daily dose, or giving the dose earlier in the day). Serious side effects (eg, hallucinations and abnormal movements) require discontinuation of medication. To avoid potential drug–food interactions and absorption issues, stimulants should be given 30 to 60 minutes before eating.

Growth suppression or delay is a major concern for parents of children taking stimulants. Growth delay appears to be transient and to resolve by midadolescence, but more data are needed to resolve this issue. Another concern is risk of substance abuse with stimulant use. A diagnosis of ADHD alone increases the risk of substance abuse in adolescents and adults. However, stimulant use has not been shown to further increase this risk but actually may decrease this risk, provided ADHD is treated adequately.

The choice of ADHD medication should be made based on the patient’s condition, prescriber’s familiarity with the medications, ease of administration, and cost. Stimulants should be used as first-line agents in most ADHD patients, although studies in groups of patients have shown no clear advantage of one stimulant over another.

Nonstimulants

Atomoxetine Atomoxetine is approved for the treatment of ADHD in both children and adults. In clinical studies, it demonstrated superior efficacy over placebo and either equivalent efficacy compared with a suboptimal immediate-release methylphenidate dose or inferior to Concerta. Atomoxetine may be used as a second- or third-line medication for ADHD.

Atomoxetine selectively inhibits the reuptake of adrenergic neurotransmitters, principally norepinephrine. Atomoxetine is metabolized through the cytochrome P450 (CYP) 2D6 pathway. Concurrent use of certain antidepressants (ie, fluoxetine, paroxetine) may inhibit this enzyme and necessitate slower dose titration of atomoxetine. Approximately 5% to 10% of the population are CYP2D6 poor metabolizers, and atomoxetine’s half-life is increased significantly in this population. The recommended dosing for atomoxetine depends on patient weight and is given once or twice daily (see Table 42–1). In poor metabolizers, atomoxetine should be dosed once daily at 25% to 50% of the dose typically used in normal metabolizers. The maximum therapeutic effect of atomoxetine may take up to 4 weeks, significantly longer than with stimulants. Common side effects of atomoxetine are similar to those of stimulants. Some studies have reported an increase in blood pressure and heart rate. It can slow growth rate and cause weight loss; thus, height and weight should be monitored routinely in children (see Table 42–2). Atomoxetine’s labeling includes warnings about severe hepatotoxicity and increased association with suicidal thinking.

Atomoxetine can be given once daily in many patients. It appears to lack any abuse potential and is not a controlled substance. One big disadvantage of atomoxetine is cost compared with other ADHD medications (Table 42–3).

</table>

ECG, electrocardiography; GI, gastrointestinal.

Because of the high cost, lack of long-term efficacy data, and few comparison studies with stimulants, atomoxetine should be advocated only if the patient has failed or is intolerant to stimulant therapy.

**Bupropion** Bupropion is a monocyclic antidepressant that weakly inhibits the reuptake of norepinephrine and dopamine. It is effective for symptoms of ADHD in children, and preliminary results suggest it may be as effective as methylphenidate.26,27 Similar results have been shown in adults.26 Bupropion is well tolerated with minimal side effects (eg, insomnia, headache, nausea, and tremor) which typically disappear with continuation of therapy and with slow titration of dose. Bupropion can worsen tics and movement disorders. It is a rational choice in an ADHD patient with comorbid depression.26 However, seizures have been associated with bupropion doses greater than 6 mg/kg/day.28 Seizures related to high doses can be minimized by reducing the dose or switching to a longer-acting formulation. Bupropion can increase the risk of suicidal ideation and is contraindicated in patients with seizure and eating disorders.

**Clonidine and Guanfacine** Clonidine and guanfacine are central α<sub>2</sub>-adrenergic agonists that inhibit the release of norepinephrine presynaptically. Both of these agents are less effective than stimulants in treating ADHD but typically are used as adjuncts to stimulants to control disruptive or aggressive behavior and alleviate insomnia.29 The effects of immediate-release guanfacine typically last 3 to 4 hours longer than immediate-release clonidine, and the drug requires less frequent dosing. Extended-release formulations of guanfacine (Intuniv) and clonidine

(Kapvay) were developed to minimize dosing frequency and improve treatment of anger, hostility, and irritability in patients with ADHD. Similar to other nonstimulants, these two dosage forms can also be used in patients who are intolerant to stimulants. However, use of these dosage forms is limited because of a lack of comparative trials to stimulants and high cost. Common side effects with clonidine and guanfacine are low blood pressure and sedation. Sedation generally subsides after 2 to 3 weeks of therapy. Rarely, severe side effects such as bradycardia, rebound hypertension, irregular heart beats, and sudden death have been reported.

**Pharmacoeconomic and Treatment Adherence Considerations**

- Annual health care costs of patients with ADHD are more than double those of patients without ADHD. The financial burden...
Perform a complete medical history, home assessment, and blood pressure. Use physical examinations or liver function tests as appropriate to monitor for adverse effects. In children being considered for ADHD pharmacotherapy, obtain baseline electrocardiograms (ECGs) when known or suspected cardiac disease exists or the clinician judges it necessary. Typically, the family does not qualify for medical assistance, and they can hardly afford their monthly expenses.

Wt: 25.7 kg (56.5 lb)
Allergies: None known
Ht: 3'10" (119 cm)
BP: 99/59 mm Hg
P: 92 beats/min

The family does not qualify for medical assistance, and they can hardly afford their monthly expenses.

What stimulants and nonstimulants are available that might control this child’s symptoms?
Which ADHD medications should you be concerned about using?
What medications will maximize efficacy, facilitate adherence, minimize potential side effects, and offer an acceptable cost?
What baseline assessment do you need before starting stimulant therapy?
What are important counseling points to discuss with the parents before starting any ADHD medication?

PatientCareProcess

Patient Assessment:
- Suspected ADHD: evaluate patient for signs and symptoms of hyperactivity-impulsivity and/or inattentiveness.
- Utilize patient symptoms and parent-teacher evaluation to determine if the patient meets the DSM-5 criteria for ADHD.
- Perform a complete medical history, home assessment, physical, and neurological examination. Include blood pressure, pulse, and height and weight measurements. A baseline ECGs may be obtained in children when known or suspected cardiac disease exists. What is the patient’s age?

Therapy Evaluation:
- Evaluate current and past medications for effectiveness and side effects. Does the patient have clear indications or any contraindications for therapy?
- Evaluate the cost effectiveness/burden of current therapy and the patient’s ability to remain adherent to therapy.
- Assess for adherence and drug interactions.

Care Plan Development:
- If patient is younger than 6 years, initiate behavioral modification therapy before starting low-dose methylphenidate (see Table 42–1). Start older patients on low-dose stimulant therapy (see Table 42–1).
- Continuously stress the importance of adherence.
- Consider switching to a different stimulant formulation if initial stimulant is not effective (see Table 42–1).
- A trial of at least two stimulants should be attempted before a nonstimulant is considered.
- Reevaluate the diagnosis if all treatment attempts fail.
- Educate the patient’s parents and/or caregivers that behavioral therapy is not as effective as stimulant therapy and about the growth delay and substance abuse risks with stimulants.

Follow-up Evaluation:
- Perform a general physical examination yearly and monitor blood pressure quarterly in adults.
- Evaluate for improvement in behavioral modification therapy patients every 3 months. Obtain information from parent/teacher rating scales.
- Measure effectiveness and safety (side effect profile) of stimulant therapy monthly for the first 3 months. Has the patient’s behavior improved? Is the patient experiencing any adverse effects?

Review medical history and obtain height, weight, heart rate, and blood pressure at each visit.

Effectiveness of treatment and potential effects on height, weight, pulse, and blood pressure. Use physical examinations or liver function tests as appropriate to monitor for adverse effects. In children being considered for ADHD pharmacotherapy, obtain baseline electrocardiograms (ECGs) when known or suspected cardiac disease exists or the clinician judges it necessary.

OUTCOME EVALUATION
Carefully document core ADHD symptoms at baseline to provide a reference point from which to evaluate effectiveness of treatment. Improvement in individualized patient outcomes are desired, such as (a) family and social relationships, (b) disruptive behavior, (c) completing required tasks, (d) self-motivation, (e) appearance, and (f) self-esteem. Elicit evaluations of the patient’s behavior from family, school, and social environments in order to assess these outcomes. Using standardized rating scales (eg, Conners Rating Scales—Revised, Brown Attention-Deficit Disorder Scale, and Inattentive-Overactive with Aggression [IOWA] Conners Scale) in both children and adults with ADHD helps to minimize variability in evaluation. After initiation of pharmacotherapy, evaluate every 2 to 4 weeks to determine...
therapeutic benefits will be seen within days of initiating stimulants and within 1 or 2 months of starting bupropion and atomoxetine. When a maintenance dose has been achieved, schedule follow-up visits every 3 months. At these visits, assess height and weight, and screen for possible adverse drug effects. If a patient has failed to respond to multiple agents, reevaluate for other possible causes of behavior dysfunction. Counsel patients and their families that treatment generally is long term. Typically, appropriately treated patients learn to better control their ADHD symptoms as adults.

years with attention-deficit hyperactivity disorder and oppositional symptoms: a randomized double-blind, placebo-controlled trial. CNS Drugs. 2010;24(9):755–768.
LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Discuss the incidence and economic impact of diabetes.
2. Distinguish clinical differences in type 1, type 2, and gestational diabetes.
3. List screening and diagnostic criteria for diabetes.
4. Discuss therapeutic goals for blood glucose and blood pressure for a patient with diabetes.
5. Recommend nonpharmacologic therapies, including meal planning and physical activity, for patients with diabetes.
6. Compare oral agents used in treating diabetes by their mechanisms of action, time of action, side effects, contraindications, and effectiveness.
7. Select appropriate insulin therapy based on onset, peak, and duration of action.
8. Discuss the signs, symptoms, and treatment of hypoglycemia.
9. Define diabetic ketoacidosis and discuss treatment goals.

INTRODUCTION

**Diabetes mellitus (DM)** describes a group of chronic metabolic disorders characterized by hyperglycemia that may result in long-term microvascular and neuropathic complications. These complications contribute to diabetes being the leading cause of (a) new cases of blindness among adults, (b) end-stage renal disease, and (c) nontraumatic lower limb amputations. Macrovascular complications (coronary artery disease, peripheral vascular disease, and stroke) are also associated with DM.

EPIEDEMOLOGY AND ETIOLOGY

DM affects an estimated 29.1 million persons in the United States, or 9.3% of the population. Although an estimated 21 million persons have been diagnosed, another 8.1 million have DM but are unaware they have the disease. The total financial impact of DM in 2012 was approximately $245 billion, with direct medical costs equaling $176 billion (2.3 times higher than what expenditures would be in the absence of diabetes) and indirect costs secondary to disability, work loss, and premature mortality equaling $69 billion.

DM is characterized by a complete lack of insulin, a relative lack of insulin, or insulin resistance as well as disorders of other hormones. These defects result in an inability to use glucose for energy. The increasing prevalence of DM is partly caused by three influences: lifestyle, ethnicity, and age.

Lifestyle

A sedentary lifestyle coupled with greater consumption of high-fat, high-carbohydrate foods, and larger portion sizes have resulted in increasing rates of persons being obese. Current estimates indicate that 34.9% of the US population is obese when obesity is defined as a body mass index (BMI) of greater than 30 kg/m². In a 2008 survey, the Centers for Disease Control and Prevention (CDC) found that 25.4% of American adults spent none of their free time being physically active.

Ethnicity

In addition to current lifestyle trends and increased body weight, certain ethnic groups are at a disproportionately high risk for developing DM. The risk of diabetes is 18% higher among Asian Americans, 68% higher among Hispanics, and 74% higher among non-Hispanic Blacks compared with non-Hispanic White adults. New cases of DM are diagnosed at a higher rate among United States minority populations than in non-Hispanic Whites.

Age

The third factor contributing to the increased prevalence of type 2 DM (T2DM) is age. In 2012, 11.2 million people in the United States who were 65 years of age or older had diabetes compared with only 208,000 younger than age 20 years. As the population ages, the incidence of T2DM is expected to increase.
**Type 1 DM (T1DM) is usually diagnosed before age 30 years but can develop at any age.** Autoimmune destruction of the β cells causes insulin deficiency. T2DM accounts for approximately 90% to 95% of all diagnosed cases of DM, is progressive in its development, and is often preceded by an increased risk for diabetes (previously known as prediabetes). A combination of insulin deficiency, insulin resistance, and other hormonal irregularities, primarily involving glucagon, are key problems with T2DM. The majority of people with T2DM are overweight, and an increasing number of cases in children have been observed.

T1DM is an autoimmune disease in which insulin-producing β cells in the pancreas are destroyed, leaving the individual insulin deficient. Individuals with T1DM may develop islet cell antibodies, insulin autoantibodies, glumatic acid dehydrogenase autoantibodies, protein tyrosine phosphatase autoantibodies, or zinc transporter protein autoantibodies, though most laboratories do not have reliably sensitive or specific assays to measure all five. As more β cells are destroyed, glucagon metabolism becomes compromised because of reduced insulin release after a glucose load. At the time of diagnosis of T1DM, it is commonly believed that most patients have an 80% to 95% loss of β-cell function.

The remaining β-cell function at diagnosis creates a “honeymoon period” during which smaller amounts of insulin are required to control glucose levels. After this, remaining β-cell function is lost, and patients become completely insulin deficient and require more exogenous insulin.

**Latent autoimmune diabetes in adults (LADA)**, slow-onset type 1, or type 1.5 DM, is a form of autoimmune T1DM that occurs in individuals older than the usual age of T1DM onset. Patients often are mistakenly thought to have T2DM because the person is older and may respond initially to treatment with oral blood glucose–lowering agents. These patients do not have insulin resistance, but antibodies are present in the blood that are known to destroy pancreatic β cells. C-peptide, a surrogate marker for insulin secretion, may be used to establish or verify a diagnosis of T1DM. When C-peptide levels are drawn, a simultaneous blood glucose level should also be taken.

**Categories of increased risk for diabetes** (commonly referred to as prediabetes) include impaired fasting glucose (IFG), impaired glucose tolerance (IGT), or hemoglobin A1c (A1c) between 5.7% and 6.4% (0.057 and 0.064; 39 and 46 mmol/mol hemoglobin [Hgb]). IfG is defined as having a fasting blood glucose (FBG) level between 100 and 125 mg/dL (5.6 and 6.9 mmol/L). IGT is defined by a postprandial blood glucose level between 140 and 199 mg/dL (7.8 and 11.0 mmol/L). The development of IFG, IGT, or A1c between 5.7% and 6.4% (0.057 and 0.064; 39 and 46 mmol/mol) places the individual at high risk of eventually developing diabetes.

T2DM is usually slow and progressive in its development. Risk factors for T2DM include:
- First-degree family history of DM (ie, parents or siblings)
- Overweight or obese
- Habitual physical inactivity
- Race or ethnicity (Native American, Latino or Hispanic American, Asian American, African American, and Pacific Islanders)
- Previously identified IFG, IGT, or A1c between 5.7% and 6.4% (0.057 and 0.064 or 39 and 46 mmol/mol Hgb)
- Hypertension (greater than or equal to 140/90 mm Hg or on therapy for hypertension)

- High-density lipoprotein (HDL) cholesterol less than 35 mg/dL (0.91 mmol/L) and/or a triglyceride level greater than 250 mg/dL (2.83 mmol/L)
- History of gestational diabetes or delivery of a baby weighing greater than 4 kg (9 lb)
- History of cardiovascular disease
- History of polycystic ovarian syndrome
- Other conditions associated with insulin resistance (eg, acanthosis nigricans)

**Gestational diabetes mellitus** (GDM) is defined as glucose intolerance in women during pregnancy. Clinical detection of and therapy for GDM are important because blood sugar control produces significant reductions in adverse maternal, fetal, and neonatal outcomes.

Diabetes from other causes includes genetic defects in β-cell function, genetic defects in insulin action, diseases of the exocrine pancreas such as cystic fibrosis, and drug- or chemical-induced diabetes. Drugs that may cause increased blood glucose include glucocorticoids, pentamidine, nicotinic acid, ß-adrenergic agonists, thiazides, phenytoin, clozapine, olanzapine, and γ-interferon. Although the use of these medications is not contraindicated in persons with DM, caution and awareness of the effects on blood glucose should be taken into account when managing these patients.

**PATHOPHYSIOLOGY**

**Normal Carbohydrate Metabolism**

The body’s main fuel source is glucose. Cells metabolize glucose completely through glycolysis and the Krebs cycle, producing adenosine triphosphate (ATP) as energy. Glucose is stored in the liver and muscles as glycogen. Glycogenolysis converts stored glycogen back to glucose. Glucose also may be stored in adipose tissue, which may subsequently undergo lipolysis yielding free fatty acids. In the fasting state, free fatty acids supply much of the energy needs for the body except for the central nervous system, which requires glucose to function normally. Proteins also can be converted to glucose through gluconeogenesis. Homeostasis is achieved through a balance of the metabolism of glucose, free fatty acids, and amino acids to maintain a blood glucose level sufficient to provide an uninterrupted supply of glucose to the brain.

Insulin and glucagon are produced in the pancreas by cells in the islets of Langerhans. β cells make up 70% to 90% of the islets and produce insulin and amylin, whereas α cells produce glucagon. The main function of insulin is to decrease blood glucose levels. Glucagon, along with other counterregulatory hormones such as growth factor, cortisol, and epinephrine, increases blood glucose levels. Although blood glucose levels vary, the opposing actions of insulin and glucagon, along with the counterregulatory hormones, normally maintain fasting values between 79 and 99 mg/dL (4.4–5.5 mmol/L).

**Normal Insulin Action**

Fasting insulin levels in the circulation average from 43 to 186 pmol/L (6–26 μIU/mL). After food is consumed, blood glucose levels rise, and the insulin-secretion response occurs in two phases. An initial burst, known as first phase insulin response, lasts approximately 5 to 10 minutes and serves to suppress hepatic glucose production and cause insulin-mediated glucose disposal in adipose tissue. This bolus of insulin minimizes hyperglycemia during meals and during the postprandial period.
The second phase of insulin response is characterized by a gradual increase in insulin secretion, which lasts 60 to 120 minutes and stimulates glucose uptake by peripheral insulin-dependent tissues, namely muscle. Slower release of insulin allows the body to respond to the new glucose entering from digestion while maintaining blood glucose levels.

Amylin is a naturally occurring hormone that is cosecreted from β cells with insulin. People with diabetes have either a relative or complete lack of amylin. Amylin has three major mechanisms of action: suppression of postmeal glucagon secretion; regulation of the rate of gastric emptying from the stomach to the small intestine, which increases satiety; and regulation of plasma glucose concentrations in the bloodstream.

► Impaired Insulin Secretion

A pancreas with normal β-cell function is able to adjust insulin production to maintain normal blood glucose levels. In T2DM, more insulin is secreted to maintain normal blood glucose levels until eventually the pancreas can no longer produce sufficient insulin. The resulting hyperglycemia is enhanced by extremely high insulin resistance, pancreatic burnout in which β cells lose functional capacity, or both. Impaired β-cell function results in a reduced ability to produce a first-phase insulin response sufficient to signal the liver to stop producing glucose. Over time, patients with T2DM experience progressive β-cell death and many require exogenous insulin to maintain blood glucose control.

► Insulin Resistance

Insulin resistance is the primary factor that differentiates T2DM from other forms of diabetes. Insulin resistance may be present for several years prior to the diagnosis of DM and can continue to progress throughout the course of the disease. Resistance to insulin occurs in adipose tissue, skeletal muscle and the liver. Insulin resistance in the liver poses a double threat because the liver becomes nonresponsive to insulin for glucose uptake, and hepatic production of glucose after a meal does not cease, leading to elevated fasting and postmeal blood glucose levels.

► Metabolic Syndrome

Insulin resistance has been associated with a number of other cardiovascular risks, including abdominal obesity, hypertension, dyslipidemia, hypercoagulation, and hyperinsulinemia. The clustering of these risk factors has been termed metabolic syndrome. Criteria defining the metabolic syndrome as established by the International Diabetes Federation are summarized in Table 43–1. Patients having these additional risk factors have been found to be at much higher cardiovascular risk than would be expected from the individual components of the syndrome.

► Incretin Effect

When nutrients enter the stomach and intestines, incretin hormones are released, which stimulate insulin secretion. This so-called incretin effect is mediated by two hormones, glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinoctropic peptide (GIP), with GLP-1 being studied the most. GLP-1 is secreted by the L cells of the ileum and colon primarily, and GIP is secreted by the K cells. GLP-1 secretion is caused by endocrine and neural signals started when nutrients enter the gastrointestinal (GI) tract. Within minutes of food ingestion, GLP-1 levels rise rapidly. A glucose-dependent release of insulin occurs, and the dipeptidyl peptidase-4 (DPP-4) enzyme cleaves GLP-1 rapidly to an inactive metabolite. Much of the research on glucose-lowering products involves prolonging the action of GLP-1. Other glucose-lowering effects of GLP-1 include suppression of glucagon, slowing gastric emptying, and increasing satiety.

CLINICAL PRESENTATION AND DIAGNOSIS

Screening

Currently, the American Diabetes Association (ADA) recommends routine screening for T2DM every 3 years in all adults starting at 45 years of age. Testing for T2DM should be considered, regardless of age, in adults who have a BMI greater than or equal to 25 kg/m² (or BMI greater than or equal to 23 kg/m² for
Table 43–2

American Diabetes Association Screening Recommendations for Diabetes

Asymptomatic Type 1
The ADA does not recommend screening for T1DM because of the low incidence in the general population and due to the acute presentation of symptoms.

Asymptomatic Type 2
1. The ADA recommends screening for T2DM every 3 years in all adults beginning at 45 years of age, particularly in those with a BMI ≥ 25 kg/m² (or BMI ≥ 23 kg/m² for Asian Americans).
2. Testing should be considered for persons younger than 45 years of age or more frequently in individuals who are overweight (BMI ≥ 25 kg/m² for the general population and ≥ 23 kg/m² for Asian Americans) and have additional risk factors:
   - Habitually inactive
   - First-degree relative with diabetes
   - Member of a high-risk ethnic population (eg, African American, Latino, Native American, Asian American, Pacific Islander)
   - Delivered a baby weighing > 4.1 kg (9 lb) or previous diagnosis of GDM
   - Hypertensive (≥ 140/90 mm Hg)
   - HDL cholesterol level less than 35 mg/dL (0.91 mmol/L) and/or triglyceride level > 250 mg/dL (2.83 mmol/L)
   - Polycystic ovary syndrome
   - Previous IGT or IFG
   - Other clinical conditions associated with insulin resistance (eg, acanthosis nigricans)
   - History of cardiovascular disease

Type 2 in Children and Adolescents
Criteria:
- Overweight (BMI > 85th percentile for age and sex, weight for height > 85th percentile, or weight > 120% of ideal for height)
Plus any two of the following risk factors:
- Family history of T2DM in first- or second-degree relatives
- Race or ethnicity (Native American, African American, Latino or Hispanic American, Asian American, Pacific Islander)
- Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, or polycystic ovary disease)
- Maternal history of diabetes or GDM during child’s gestation

Age of initiation
Age 10 years or at onset of puberty, if puberty occurs at a younger age
Frequency of testing:
- Every 3 years
- Test method: FPG or OGTT possibly more suitable than A₁c

Gestational diabetes
1. Screen for undiagnosed T2DM at first prenatal visit in those with risk factors using standard criteria
2. All women should be screened with an OGTT between weeks 24 and 28 of gestation

A₁c, hemoglobin A₁c; ADA, American Diabetes Association; BMI, body mass index; FPG, fasting plasma glucose; GDM, gestational diabetes mellitus; HDL, high-density lipoprotein; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

Asian Americans) and one or more additional risk factors. The ADA does not currently recommend widespread screening for T1DM, although measurement of islet autoantibodies may be appropriate for high-risk individuals, including those who have relatives with T1DM. See Table 43–2 for complete screening guidelines.

Gestational Diabetes

All pregnant women who have risk factors for T2DM should be screened for undiagnosed T2DM at their first prenatal visit using standard diagnostic criteria. Any woman found to have diabetes at that early point in pregnancy is considered to have T2DM, not GDM. All other pregnant women, not currently known to have DM should be screened for GDM. Two possible strategies exist for GDM screening. They are a “one-step” 2-hour 75-gram oral glucose tolerance test (OGTT) and a “two-step” process which includes a 1-hour 50-gram nonfasting screen followed by a 3-hour 100-gram OGTT for those with a 1-hour screening glucose of greater than or equal to 140 mg/dL (7.8 mmol/L). The diagnostic criteria for the “one-step” 2-hour 75-gram OGTT are listed in Table 43–3. Any woman diagnosed with GDM should be retested at 6 to 12 weeks postpartum using the OGTT with nonpregnant diagnostic criteria.

A positive diagnosis of diabetes is made when any of the listed glucose values are exceeded. The test should be done in the morning after an 8-hour fast.

Note: these values are based on American Diabetes Association guidelines.
Table 43–4

ADA Criteria for Diagnosis of Diabetes

Symptoms of diabetes plus a casual plasma glucose concentration ≥ 200 mg/dL (11.1 mmol/L). Casual is defined as any time of day without regard to time since the last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

or

FPG ≥ 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.

or

Two-hour postload glucose ≥ 200 mg/dL (11.1 mmol/L) during an OGTT. The test should be performed as described by the WHO using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water.

or

A₁c ≥ 6.5% (0.065; 48 mmol/mol Hgb). The test should be performed in a laboratory using a method that is NGSP certified to the DCCT assay.

ADA, American Diabetes Association; A₁c, hemoglobin A₁c; DCCT, Diabetes Control and Complications Trial; FPG, fasting plasma glucose; Hgb, hemoglobin; NGSP, National Glycohemoglobin Standardization Program; OGTT, oral glucose tolerance test; WHO, World Health Organization.

In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day. The OGTT is not recommended for routine clinical use.

Diagnostic Criteria

The diagnosis of DM includes glycemic outcomes exceeding threshold values with one of three testing options (Table 43–4). Confirmation of abnormal values must be made on a subsequent day for diagnosis unless unequivocal symptoms of hyperglycemia exist, such as polydipsia, polyuria, and polyphagia. Either A₁c, fasting plasma glucose (FPG), or OGTT are appropriate tests for detecting DM.

The ADA categorizes patients demonstrating A₁c between 5.7% and 6.4% (0.057 and 0.064 or 39 and 46 mmol/mol Hgb), IFG, or IGT as having increased risk for future diabetes. The categorization thresholds of glucose status for FPG determination and the OGTT are listed in Table 43–5. IFG and IGT may coexist or may be identified independently. FPG level represents hepatic glucose production during the fasting state, whereas postprandial glucose levels in the OGTT may reflect glucose uptake in peripheral tissues, insulin sensitivity, or a decreased first-phase insulin response. The OGTT identifies people with either IFG or IGT and therefore potentially more people at increased risk for DM and cardiovascular disease. The OGTT is a more cumbersome test to perform than either the A₁c or FPG; however, the efficacy of interventions for primary prevention of T2DM have been demonstrated among patients with IGT, not among those with IFG or specific A₁c levels.

Patient Encounter, Part 1

A 42-year-old African American woman presents to her physician for a follow-up appointment for her recent pregnancy. Upon questioning, she states that she was diagnosed with gestational diabetes during the pregnancy, and that two of her previous three children weighed greater than 9 pounds (~4 kg) at birth. She is currently 12 weeks postpartum and is without complaint.

PMH: Allergic rhinitis, gestational diabetes

FH: Father has diabetes, hypertension, and a history of myocardial infarction at age 54 years; mother has diabetes and a history of stroke at age 70 years; brother has hypercholesterolemia

SH: Smokes half pack per day for 10 years, but quit during her pregnancy; denies alcohol or illicit drug use; denies physical activity

Allergies: Sulfa and penicillin

Meds: Fluticasone nasal spray, one spray each nostril daily

VS: BP 114/85 mm Hg, P 82 beats/min, RR 20 breaths/min, T 37°C (98.6°F), Ht 5′ 3″ (160 cm), Wt 165 lb (75 kg)

ROS: (+) Fatigue, (–) N/V/D, HA, SOB, chest pain

What risk factors does this patient have for diabetes?

Which type of diabetes do her characteristics suggest?

What additional information is needed to diagnose this patient with diabetes?

TREATMENT

Goals of Therapy

DM treatment goals include reducing, controlling, and managing long-term microvascular, macrovascular, and neurovascular complications; preserving β-cell function; preventing acute complications from high blood glucose levels; minimizing hypo- and hyperglycemic episodes; and maintaining the patient’s overall quality of life. To achieve the majority of these goals, near-normal blood glucose levels are fundamental; thus, glycemic control remains a primary objective in diabetes management. Two landmark trials, the Diabetes Control and Complications Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS), showed that lowering blood glucose levels decreased the risk of developing chronic complications. A near-normal blood glucose level can be achieved with appropriate patient education, lifestyle modification, and medications.

Proper care of DM requires goal setting and assessment for glycemic control, self-monitoring of blood glucose (SMBG), monitoring of blood pressure and lipid levels, regular monitoring for the development of complications, dietary and exercise lifestyle modifications, and proper medication use. The complexity
of proper DM self-care principles has a dramatic impact on a patient’s lifestyle and requires a highly disciplined and dedicated person to maintain long-term control.

**Setting and Assessing Glycemic Targets**

**KEY CONCEPT** Patients and clinicians can evaluate disease state control of the patient’s diabetes by monitoring daily blood glucose values, \( A_1c \), or estimated average glucose (eAG) values, and blood pressure. SMBG enables patients to obtain their current blood glucose level at any time easily and relatively inexpensively. The \( A_1c \) test provides a weighted-mean glucose level from approximately the previous 3 months.

**Self-Monitoring of Blood Glucose** SMBG is the standard method for routinely checking blood glucose levels. Each reading provides a point-in-time evaluation of glucose control that can vary widely depending on numerous factors, including food, exercise, stress, and time of day.

By examining multiple individual points of data, patterns of control can be established. Therapy can be evaluated from these patterns, and adjustments can be made to improve overall blood glucose control. The ADA premeal plasma glucose goals are 80 to 130 mg/dL (4.4–7.2 mmol/L) and peak postprandial plasma glucose goals are less than 180 mg/dL (10.0 mmol/L). The American Association of Clinical Endocrinologists (AACE) supports tighter SMBG controls, with premeal goals of less than 110 mg/dL (6.1 mmol/L) and peak postmeal goals of less than 140 mg/dL (7.8 mmol/L). For patients using multiple daily insulin injections or insulin pump therapy, SMBG may need to be performed six to eight times per day. The optimal frequency of testing in patients using less frequent insulin injections, noninsulin therapies, or medical nutrition therapy (MNT) is less clear. Patients with arthritis or other conditions that decrease dexterity may prefer larger meters with little or no handling of glucose strips. Younger patients or busy professionals may prefer smaller meters with features such as faster results, larger memories, reminder alarms, and downloading capabilities. Continuous glucose sensors are now available that work with or independently of insulin pumps. These monitors provide glucose readings, primarily through interstitial fluid (ISF). A small sterile disposable glucose-sensing device called a sensor is inserted into the subcutaneous tissues. This sensor measures the change in glucose in ISF and sends the information to a monitor, which stores the results.

**Hemoglobin \( A_1c \)** Glucose interacts spontaneously with Hgb in red blood cells to form glycated derivatives. The most prevalent derivative is \( A_1c \). Greater amounts of glycation occur when blood glucose levels increase. Because Hgb has a life span of approximately 3 months, levels of \( A_1c \) provide a marker reflecting the average glucose levels over this timeframe. The ADA goal for persons with DM is less than 7% (0.07; 53 mmol/mol Hgb), whereas the AACE supports a goal of less than or equal to 6.5% (0.065; 48 mmol/mol Hgb). Testing \( A_1c \) levels should occur at least twice a year for patients who are meeting treatment goals and four times per year for patients not meeting goals or those who have had recent changes in therapy.

**Estimated Average Glucose** The eAG is used to correlate \( A_1c \) values with readings that patients obtain from their home glucose monitors. The equation to convert from \( A_1c \) to eAG is: eAG (mg/dL) = \( 28.7 \times A_1c - 46.7 \) (or eAG [mmol/L] = \( 1.59 \times A_1c - 2.59 \) for \( A_1c \) expressed as a percentage). The goal eAG is 154 mg/dL (8.5 mmol/L), which corresponds with an \( A_1c \) of less than 7% (0.07; 53 mmol/mol Hgb).

**Ketone Monitoring** Urine and blood ketone testing is important in people with T1DM, in pregnancy with preexisting diabetes, and in GDM. People with T2DM may have positive ketones and develop diabetic ketoacidosis (DKA) if they are ill.

The presence of ketones may indicate a lack of insulin or ketoacidosis, a condition that requires immediate medical attention. When there is a lack of insulin, peripheral tissues cannot take up and store glucose. This causes the body to think it is starving, and because of excessive lipolysis, ketones, primarily \( \beta \)-hydroxybutyric acid and acetocetic acid, are produced as byproducts of free fatty acid metabolism in the liver. Glucose and ketones are osmotically active, and when an excessive amount of ketones is formed, the body gets rid of them through urine, leading to dehydration. Patients with T1DM should test for ketones during acute illness or stress or when blood glucose levels are consistently elevated above 300 mg/dL (16.7 mmol/L). This commonly occurs when insulin is omitted or when diabetes is poorly controlled due to nonadherence, illness, or other reasons. Women with preexisting diabetes before pregnancy or with GDM should check ketones using their first morning urine sample or when any symptoms of ketoacidosis such as nausea, vomiting, or abdominal pain are present. Blood ketone testing methods that quantify \( \beta \)-hydroxybutyric acid, the predominant ketone body, are available and are the preferred way to diagnose and monitor ketoacidosis. Home tests for \( \beta \)-hydroxybutyric acid are available. The specific treatment of DKA may include rehydration, correction of electrolyte imbalances, and insulin administration.

**Blood Pressure and Monitoring for Complications**

The ADA standards of medical care address many of the common comorbids conditions, as well as complications that result from the progression of DM. Table 43–6 presents goals for blood pressure measurements and monitoring parameters for complications associated with diabetes.

**General Approach to Therapy**

**Type 1 Diabetes Mellitus**

Treatment of T1DM requires providing exogenous insulin to replace the endogenous loss of insulin from the nonfunctional pancreas. Ideally, insulin therapy mimics normal insulin physiology. The basal-bolus approach attempts to reproduce basal...

$A_1c$, hemoglobin $A_1c$; ADA, American Diabetes Association; eAG, estimated average glucose; Hgb, hemoglobin.

“Peak postprandial glucose measurements should be made 1 to 2 hours after the beginning of the meal.

Insulin response using intermediate- or long-acting insulin, whereas short- or rapid-acting insulin replicates bolus release of insulin physiologically seen around a meal in nondiabetics. A number of different regimens have been used through the years to more closely follow natural insulin patterns. As a rule, basal insulin makes up approximately 50% of the total daily dose. The remaining half is provided with bolus doses around three daily meals.

Exact doses are individualized to the patient and the amount of food consumed. T1DM patients frequently are started on about 0.6 unit/kg/day, and then doses are titrated until glycemic goals are reached. Most people with T1DM use between 0.6 and 1 unit/kg/day.

Currently, the most advanced form of insulin delivery is the insulin pump, also referred to as continuous subcutaneous insulin infusion (CSII). See Figure 43–1. Using rapid-acting insulin only, these pumps are programmed to provide a slow release of small amounts of insulin as the basal portion of therapy, and larger boluses of insulin are injected by the patient to account for the consumption of food. Pramlintide, a synthetic analog of the naturally occurring hormone amylin, is another injectable blood glucose–lowering medication that can be used in people with T1DM or in people with T2DM using insulin for treatment.

**Type 2 Diabetes Mellitus**

Treatment of patients with T2DM has changed dramatically over the past decade with the addition of a number of new drugs and recommendations to maintain tighter glycemic control. However, lifestyle modifications including education, nutrition, and exercise are paramount to managing the disease successfully.

**Gestational Diabetes**

An individualized meal plan consisting of three meals and three snacks per day is commonly recommended in GDM. Preventing ketosis, promoting adequate growth of the fetus, maintaining satisfactory blood glucose levels, and preventing nausea and other undesired GI side effects are desired goals in these patients. An abundance of glucose causes excessive insulin production by the fetus, which if left uncontrolled, can lead to the development of an abnormally large fetus. Infant hypoglycemia at delivery, hyperbilirubinemia, and complications associated with delivery of a large baby also may occur when blood glucose levels are not controlled adequately. Insulin should be used when blood glucose levels are not maintained adequately by diet and physical activity. Insulin detemir, insulin aspart, lispro, and regular insulin carry Category B safety ratings.

**Nonpharmacologic Therapy**

**Medical Nutrition Therapy**

MNT is considered an integral component of diabetes management and diabetes self-management education. People with DM...
should receive individualized MNT, preferably by a registered diettitian. MNT should be provided as an ongoing dialog customized to take into account cultural, lifestyle, and financial considerations.

The primary focus of MNT for patients with T1DM is matching optimal insulin dosing to carbohydrate consumption. In T2DM, the primary focus is portion control and controlling blood glucose, blood pressure, and lipids through individualizing levels of carbohydrates, saturated fats, sodium, and calories. Carbohydrates are the primary contributor to postmeal glucose levels. The percentages of fat, protein, and carbohydrate included in each meal should be individualized based on the specific goals of each patient.7

Dietary Supplements

There is insufficient evidence of efficacy for improved blood glucose control for any individual herb or supplement.7 Herbs and supplements commonly touted to improve glucose control include chromium, magnesium, vitamin D, and cinnamon. Patients will inquire about and use dietary supplements. It is important that clinicians respect the patient’s health beliefs, address their questions and concerns, and educate them on the differences between dietary supplements and prescribed therapies.

Weight Management

Moderate weight loss in patients with T2DM has been shown to reduce cardiovascular risk, as well as delay or prevent the onset of DM in those with prediabetes.2,20 The recommended primary approach to weight loss is therapeutic lifestyle change (TLC), which integrates a 7% reduction in body weight and an increase in physical activity.7 A slow but progressive weight loss of 0.45 to 0.91 kg (1–2 lb) per week is preferred.21 Although individual target caloric goals should be set, a general rule for weight loss diets is that they should supply at least 1000 to 1200 kcal/day (about 4200–5000 kJ/day) for women and 1200 to 1600 kcal/day (about 5000–6700 kJ/day) for men. Gastric reduction surgeries (gastric banding or procedures that bypass, transpose, or resect portions of the small intestine), when used as a part of a comprehensive approach to weight loss, are recommended for consideration in patients with T2DM and a BMI that exceeds 35 kg/m2.2 Two drug therapy options were recently approved, lorcaserin and phentermine/topiramate extended release, to aid weight loss in obese patients and in overweight patients with concomitant disease states such as T2DM, hypertension and dyslipidemia.16

Physical Activity

Regular physical activity has been shown to improve blood glucose control and reduce cardiovascular risk factors such as hypertension and elevated serum lipid levels.20 Physical activity is also a primary factor associated with long-term maintenance of weight loss and overall weight control. Regular physical activity also may prevent the onset of T2DM in high-risk persons.

Before initiating a physical activity program, patients should undergo a detailed physical examination, including screening for microvascular or macrovascular complications that may be worsened by a particular activity. Initiation of physical activities in an individual with a history of a sedentary lifestyle should begin with a modest increase in activity. Walking, swimming, and cycling are examples of low-impact exercises that could be encouraged. At the same time, gardening and usual housecleaning tasks are good exercises as well. Recommended physical activity goals for patients with T2DM include 150 minutes per week of moderate to vigorous aerobic exercise spread out during at least 3 days of the week with no more than two consecutive days between bouts of aerobic activity and moderate to vigorous resistance training at least 2 to 3 days per week.7

Psychological Assessment and Care

Mental health and social state have been shown to have an impact on a patient’s ability to carry out DM management care tasks.7 Clinicians should incorporate psychological assessment and treatment into routine care. The ADA guidelines recommend ongoing psychological screening, including determining the patient’s attitudes regarding DM; expectations of medical management and outcomes; mood and affect; general and diabetes-related quality of life; and financial, social, and emotional resources. Patients demonstrating poor self-management should be screened for diabetes-related distress, depression, anxiety, an eating disorder, and/or cognitive impairment.

Immunizations

Influenza and pneumonia are common preventable infectious diseases that increase mortality and morbidity in persons with chronic diseases, including DM. Yearly influenza vaccinations, commonly called flu shots, are recommended for all patients with DM 6 months of age or older.7 Pneumococcal vaccination with the polysaccharide vaccine 23 is also recommended for patients with DM who are 2 years of age or older as a one-time vaccination. Adults aged greater than or equal to 65 years of age who have not previously been vaccinated should receive the pneumococcal conjugate vaccine 13 followed by the polysaccharide vaccine 6 to 12 months later. Adults who have received the polysaccharide vaccine should receive the conjugate vaccine after greater than or equal to 12 months. The hepatitis B vaccine series should also be administered as per the CDC’s recommendations in patients with diabetes.

Pharmacotherapy

Figures 43–2 and 43–3 summarize treatment algorithms for T2DM.16,18 While similar, these treatment algorithms differ in that, at this time, the ADA guidelines do not advocate for the use of several treatment options that the AACE guidelines include; namely, colesevlam, α-glucosidase inhibitors, and bromocriptine. Also, the AACE guidelines take a more aggressive approach, including consideration for starting a patient on two drugs if their presenting A1c is greater than or equal to 7.5% (0.075; 58 mmol/mol Hgb). While the ADA guidelines include metformin alone as the first-line therapy option for T2DM, the AACE guidelines include six other noninsulin initial therapy options as possibilities. As noted earlier, the AACE guidelines also advocate for lower A1c and SMBG goals. Because T2DM generally tends to be a progressive disease, blood glucose levels will eventually increase, making insulin therapy the eventual required therapy in many patients. Recently, the ADA added selective sodium-dependent glucose cotransporter-2 (SGLT-2) inhibitors as second and third line add-on options.7 The addition of GLP-1 receptor agonists is now recognized by the ADA as an alternative to mealtime insulin in those requiring more complex injectable regimens. Figure 43–4 is one illustration of a way to start insulin therapy while keeping the patient on some oral medications.19 This is usually done when several oral agents have been used with inadequate glucose-lowering results.

Oral and injectable agents are available to treat patients with T2DM who are unable to achieve glycemic control
This action results in membrane depolarization, allowing an influx of calcium to cause the translocation of secretory granules of insulin to the cell surface, and enhances insulin secretion in a non-glucose-dependent manner. Insulin is then transported through the portal vein to the liver, suppressing hepatic glucose production. These drugs are classified as being either first- or second-generation agents. Both classes of sulfonylureas are equally effective when given at equipotent doses. Today, the vast majority of patients receiving a sulfonylurea are prescribed a second-generation agent. All sulfonylureas undergo hepatic biotransformation, with most agents being metabolized by the cytochrome P450 2C9 pathway. The first-generation sulfonylureas are more likely to cause drug interactions than second-generation agents. All sulfonylureas, except tolbutamide, require a dosage adjustment or are

### Sulfonylureas

Sulfonylureas enhance insulin secretion by blocking ATP-sensitive potassium channels in the cell membranes of pancreatic β cells. This action results in membrane depolarization, allowing an influx

through meal planning and physical activity. Table 43–7 lists the oral agents and Table 43–8 lists each noninsulin drug class with site of action and mechanism of action. The various classes of blood glucose–lowering agents target different organs and have different mechanisms of action. Each of these agents may be used individually or in combination with other medications that target different organs for synergistic effects. In addition to single agent products, there are many combination products marketed as well.

### Sulfonylureas

Sulfonylureas enhance insulin secretion by blocking ATP-sensitive potassium channels in the cell membranes of pancreatic β cells. This action results in membrane depolarization, allowing an influx

- **Table 43–7**
- **Table 43–8**
- **FIGURE 43–2.** Patient centered approach to antihyperglycemic therapy in type 2 diabetes as per the American Diabetes Association/European Association for the Study of Diabetes. Begin with lifestyle changes and add metformin monotherapy at, or soon after, diagnosis. If HbA1c target is not achieved after 3 months, consider one of five treatment options combined with metformin: a SU, TZD, DPP-4 i, GLP-1 RA, or basal insulin. Choice is based on patient and drug characteristics. Consider beginning at this stage in patients with HbA1c greater than 9% (0.09; 75 mmol/mol Hgb). Consider meglitinides in patients with irregular meal schedules or who develop postprandial hypoglycemia on sulfonylureas. Consider additional potential adverse effects. Usually a basal insulin in combination with noninsulin agents. Some noninsulin agents may be continued with insulin. Consider beginning at this stage if patient presents with glucose greater than 300 mg/dL (16.7 mmol/L). (DPP-4, dipeptidyl peptidase-4; DPP-4 i, dipeptidyl peptidase-4 inhibitor; Fx, fractures; GI, gastrointestinal; GLP-1, glucagon-like peptide-1; GLP-1 RA, glucagon-like peptide-1 receptor agonist; HbA1c, hemoglobin A1c; HF, heart failure; SU, sulfonylurea; TZD, thiazolidinedione.) (From Inzucchi SE, Bergenstal RM, Buse JB, et al. Management of hyperglycemia in type 2 diabetes: A patient-centered approach. Diabetes Care. 2012;35:1364–1379, with permission.)
not recommended in renal impairment. In elderly patients or those with compromised renal or hepatic function, lower starting dosages are necessary.

Sulfonylureas’ blood glucose–lowering effects can be observed in both fasting and postprandial levels. Monotherapy with these agents generally produces a 1.5% to 2% (0.015–0.02 or 17–22 mmol/mol Hgb) decline in \( A_1c \) concentrations and a 60 to 70 mg/dL (3.3–3.9 mmol/L) reduction in FBG levels. Secondary failure with these drugs occurs as a result of continued pancreatic \( \beta \)-cell destruction. One limitation of sulfonylurea therapy is the inability of these products to stimulate insulin release from \( \beta \) cells at extremely high glucose levels, a phenomenon called glucose toxicity. Common adverse effects include hypoglycemia and weight gain. There may be some cross-sensitivity in patients with sulfa allergy.

**Nonsulfonylurea Secretagogues (Glinides)**

Although producing the same effect as sulfonylureas, nonsulfonylurea secretagogues, also referred to as meglitinides, have a much shorter onset and duration of action. Meglitinides produce a pharmacologic effect by interacting with ATP-sensitive potassium channels on the \( \beta \) cells; however, this binding is to a receptor adjacent to those to which sulfonylureas bind.

The primary benefit of nonsulfonylurea secretagogues is in reducing postmeal glucose levels. These agents have demonstrated a reduction in \( A_1c \) levels between 0.8% and 1% (0.008 and 0.01; 9–11 mmol/mol). Because they have a rapid onset and short duration of action, they are to be taken 15 to 30 minutes before a meal.

**Biguanides**

The only biguanide approved by the Food and Drug Administration (FDA) and currently available in the United States is metformin. This agent is thought to lower blood glucose by decreasing hepatic glucose production and increasing insulin sensitivity in both hepatic and peripheral muscle tissues; however, the exact mechanism of action remains unknown. It has been shown to reduce \( A_1c \) levels by 1.5% to 2% (0.015–0.02; 17–22 mmol/mol...
Hgb) and FPG levels by 60 to 80 mg/dL (3.3–4.4 mmol/L) when used as monotherapy. Unlike the sulfonylureas, metformin retains the ability to reduce fasting glucose levels when they are over 300 mg/dL (16.7 mmol/L). Metformin does not affect insulin release from β cells of the pancreas, so hypoglycemia is not a common side effect.

Metformin significantly reduced all-cause mortality and the risk of stroke in overweight patients with T2DM compared with intensive therapy with sulfonylurea or insulin in the UKPDS. It also reduced diabetes-related death and myocardial infarction compared with a conventional therapy arm. Given that metformin is the only oral antihyperglycemic medication proven to reduce mortality and is available generically, metformin is considered foundational therapy along with lifestyle modification for T2DM and is often used in combination with other antihyperglycemics for synergistic effects.

GLP-1, glucagon-like peptide-1; SGLT-2, sodium-dependent glucose cotransporter-2.

Per US labeling, metformin is contraindicated in patients with abnormal creatinine clearance for any cause and in patients with a serum creatinine level greater than or equal to 1.4 mg/dL (124 μmol/L) in women and 1.5 mg/dL (133 μmol/L) in men.²² It should not be initiated in patients 80 years of age or older unless normal renal function has been established. Additionally, therapy with metformin should be withheld in patients undergoing surgery or radiographic procedures in which a nephrotoxic dye is used. Therapy should be withheld the day of the radiographic procedure, and renal function should be assessed 48 hours after the procedure. If renal function is normal, therapy may be resumed.

Primary side effects associated with metformin therapy are GI in nature, including decreased appetite, nausea, and diarrhea. These side effects can be minimized through slow titration of the dose and often subside within 2 weeks. Interference with vitamin B₁₂ absorption has also been reported.³ Metformin is thought to inhibit mitochondrial oxidation of lactic acid, thereby increasing the chance of lactic acidosis, a condition which rarely occurs. Patients at greatest risk for developing lactic acidosis include those with renal impairment and those who are of advanced age.²² Metformin should be withheld promptly in cases of hypoxemia, sepsis, or dehydration. Patients should avoid consumption of excessive amounts of alcohol while taking metformin, and use of the drug should be avoided in patients with liver disease.

**Thiazolidinediones**

Thiazolidinediones (TZDs) are known to increase insulin sensitivity by stimulating peroxisome proliferator-activated receptor gamma (PPAR-γ) which increases insulin sensitivity and decreases plasma fatty acids. As monotherapy, TZDs reduce FPG levels by around 60 to 70 mg/dL (3.3–3.9 mmol/L), and the effect on A₁c is an up to 1.5% (0.015; 17 mmol/mol Hgb) reduction.⁴ The onset of action for TZDs is delayed for several weeks and may require up to 12 weeks before maximum effects are observed.

Both pioglitazone and rosiglitazone minimally increase HDL cholesterol, 2.4 to 5.2 mg/dL (0.06–0.13 mmol/L) on average.²⁴ Pioglitazone has been shown to decrease serum triglycerides (TG) 51.9 mg/dL (0.59 mmol/L) on average, but an increase in TG has been observed with rosiglitazone. Low-density lipoprotein (LDL) cholesterol concentrations increase by 12.3 mg/dL (0.32 mmol/L) and 21.3 mg/dL (0.55 mmol/L) on average with pioglitazone and rosiglitazone, respectively.

The TZDs may produce fluid retention and edema. Thus, these drugs are contraindicated in situations in which an increased fluid volume is detrimental such as heart failure. Fluid retention appears to be dose related and increases when combined with insulin therapy.

A few cases of hepatotoxicity have been reported with rosiglitazone and pioglitazone. Patients with a baseline elevated alanine aminotransferase (ALT) level should be started on TZD therapy with caution. Therapy should be stopped if ALT levels exceed three times the upper normal while on therapy and remain there, especially if the patient’s total bilirubin is also elevated.⁸

Increased rates of upper and lower limb fractures are known to occur with TZD therapy. Premenopausal anovulatory women may begin to ovulate on TZD therapy, and therefore counseling regarding this should be provided to all women capable of becoming pregnant. A slight increased risk for bladder cancer has been noted with pioglitazone therapy, especially among men and smokers.

A 2007 meta-analysis conducted by Nissen and colleagues reported a significantly greater risk of myocardial infarction with rosiglitazone compared with other oral agents.²¹ A subsequent prospective study found rosiglitazone use to be associated with a nonsignificant increase in myocardial infarction risk and a nonsignificant reduction in stroke, but a trend toward increased cardiovascular risk in those patients with a history of ischemic heart disease.²⁶ In May 2011, the FDA chose to restrict access and distribution of rosiglitazone to the Avandia-Rosiglitazone Medicines Access Program.²² Following receipt of subsequent data that showed the risk of heart attack with rosiglitazone was not increased as compared with metformin and sulfonylureas, the FDA lifted their restrictions on the drug in November 2013.

**α-Glucosidase Inhibitors**

Acarbose and miglitol are α-glucosidase inhibitors which compete with the enzymes of the small intestines that break down complex carbohydrates. These drugs delay absorption of carbohydrates and reduce postprandial blood glucose concentrations as much as 40 to 50 mg/dL (2.2 to 2.8 mmol/L); however, A₁c reductions range only from 0.3% to 1% (0.003–0.01; 3–11 mmol/mol Hgb).³ High incidences of GI side effects, including flatulence (42%–74%), abdominal discomfort (12%–19%), and diarrhea (29%–31%), have limited their use.²² Low initial doses followed by gradual titration may minimize GI side effects.
The α-glucosidase inhibitors are contraindicated in patients with chronic intestinal diseases including inflammatory bowel disease. In addition, neither drug in this class is recommended for patients with a serum creatinine greater than 2 mg/dL (177 μmol/L).

**Dipeptidyl Peptidase-4 Inhibitors (Gliptins)**

The dipeptidyl peptidase-4 (DPP-4) inhibitors (sitagliptin, saxagliptin, linagliptin, and alogliptin) are approved as adjunct to diet and exercise to improve glycemic control in adults with T2DM. They lower blood glucose concentrations by inhibiting DPP-4, the enzyme that degrades endogenous GLP-1, thereby increasing the amount of endogenous GLP-1. The blood glucose-lowering effect of the gliptins is primarily on postprandial levels. Typical A₁c reductions are 0.7% to 1% (0.007–0.01; 8–11 mmol/mol Hgb). Common adverse effects include headache and nasopharyngitis. Hypoglycemia is not a common adverse effect with these agents because insulin secretion results from GLP-1 activation caused by meal-related glucose detection and not from direct pancreatic β-cell stimulation. Acute pancreatitis, including hemorrhagic and necrotizing pancreatitis, has been reported in patients taking gliptins.

**Selective Sodium-Dependent Glucose Cotransporter-2 (SGLT-2) Inhibitors**

Canagliflozin, dapagliflozin, and empagliflozin, SGLT-2 inhibitors, are approved as adjunct to diet and exercise to improve glycemic control in adults with T2DM. The SGLT-2 receptor is responsible for 90% of the active glucose reabsorption of the kidney’s proximal tubule. By inhibiting this receptor, glucose reabsorption is decreased. Glucose passes into the urine, serum glucose is lowered and modest weight loss is promoted. Typical A₁c reductions are 0.7% to 1.3% (0.007–0.013; 8–14.3 mmol/mol Hgb). Possible adverse reactions include urinary tract infections, genital mycotic infections, increased urination, hypoten- sion, and increased serum creatinine.

**Central-Acting Dopamine Agonist**

A quick release formulation of the central-acting dopamine agonist, bromocriptine, is approved for the treatment of T2DM. The mechanism of action for how bromocriptine regulates glycemic control is unknown, but data indicate that bromocriptine administered in the morning improves insulin sensitivity, and this is likely a result of its affect on dopamine oscillations. When used to treat patients with T2DM, bromocriptine should be taken 2 hours after waking in the morning with food. A modest A₁c reduction of 0.3% to 0.6% (0.003–0.006; 3–7 mmol/mol Hgb) can be expected from this drug. Main side effects include rhinitis, dizziness, asthma, headache, sinusitis, constipation, and nausea. Contraindications include syncopal migraine and women who are nursing.

**Bile Acid Sequestrants**

Colestevalam is the only bile acid sequestrant currently approved as an adjunctive therapy to improve glycemic control in conjunction with diet, exercise, and insulin or oral agents for the treatment of T2DM. It acts on the intestinal lumen to bind bile acid, but the drug’s exact mechanism that results in plasma glucose lowering is unknown. An A₁c reduction of approximately 0.4% (0.004; 5 mmol/mol Hgb) and a FPG reduction of about 5 to 10 mg/dL (0.3–0.6 mmol/L) can be expected when colesvelem is added. Common adverse effects include constipation and dyspepsia. Drug–drug interactions are possible because of absorption and can be particularly important in patients who are taking levothyroxine, gluburide, oral contraceptives, phenytoin, warfarin, and digoxin. These medications should not be taken together, and they should be separated by at least 4 hours before dosing colesvelam. Malabsorption of fat-soluble vitamins (A, D, E, and K) is also a concern.

**Insulin**

Insulin is the one agent that can be used in all types of DM and has no specific maximum dose, meaning it can be titrated to suit each individual patient’s needs. Insulin is the primary treatment to lower blood glucose levels for patients with T1DM, and injected amylin can be added to decrease fluctuations in blood glucose levels. An insulin treatment algorithm for T2DM is found in Figure 43–2.

Insulin can be divided into two main classes, basal and bolus, based on their length of action to mimic endogenous insulin physiology. Most formulations are available as U-100, indicating a concentration of 100 unit/mL. Insulin is typically refrigerated, though most vials are good for 28 days at room temperature.

Specific details of insulin products are listed in Table 43–9.

The most common route of administration for insulin is subcutaneous injection using a syringe or pen device. Patients should be educated to rotate their injection sites to minimize lipo- hypertrophy, a buildup of fat that decreases or prevents proper insulin absorption. Additionally, patients should understand that the absorption rate may vary among injection sites (abdomen, thigh, arm, and buttocks) because of differences in blood flow, with absorption occurring fastest in the abdomen and slowest in the buttocks.

Insulin syringes are distinguished according to the syringe capacity, syringe markings, and needle gauge and length. Insulin pens are self-contained systems of insulin delivery. The primary advantage of the pen system is the patient does not have to draw up the dose from the insulin vial. Both insulin syringes and pens are now available with shorter needles (4–6 mm, compared to traditional lengths of 8–12.7 mm) which do not require the patient to pinch up their skin before injecting. With the no pinch technique, the needle is injected straight in at a 90-degree angle until flush with the skin. However, these products require a 10 second count to allow enough time for the insulin to be injected. This technique makes injections easier, especially the traditionally more difficult sites such as arms and buttocks.

**Bolus Insulins**

**Regular Insulin.** Regular insulin is unmodified crystalline insulin commonly referred to as natural or human insulin. It is a clear solution that has a relatively short onset and duration of action and is designed to cover insulin response to meals. On subcutaneous injection, regular insulin forms small aggregates called hexamers that undergo conversion to dimers followed by monomers before systemic absorption can occur. Patients should be counseled to inject regular insulin subcutaneously 30 minutes before consuming a meal. Regular insulin is the only insulin that can be administered intravenously (IV).

**Rapid-Acting Insulin.** Three rapid-acting injectable insulins have been approved in the United States: aspart, glulisine, and lispro. Substitution of one or two amino acids in regular insulin results in the unique pharmacokinetic properties characteristic of these agents. The onset of action of injectable rapid-acting insulins varies from 15 to 30 minutes, with peak effects occurring one to two hours after administration and is dosed before...

Inh, inhalation; IV, intravenous; OTC, over-the-counter; Rx, prescription required; SC, subcutaneous; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

...or with meals. An inhaled rapid-acting insulin was also recently approved. Its peak effect is expected to occur around 15 to 20 minutes following a dose with a duration of action of only two to three hours.

**Basal Insulins**

**Intermediate-Duration Insulin.** Neutral Protamine Hagedorn, better known as NPH insulin, is prepared by a process in which protamine is conjugated with regular insulin, rendering a product with a delayed onset but extended duration of action, and is designed to cover insulin requirements in between meals and/or overnight. With the advent of the long-acting insulins, NPH insulin use has declined because of (a) an inability to predict accurately when peak effects occur and (b) a duration of action of less than 24 hours. Additionally, protamine is a foreign protein that may increase the possibility of an allergic reaction.

NPH insulin can be mixed with regular insulin and used immediately or stored for future use. NPH insulin can be mixed with either aspart or lispro insulins, but it must be injected immediately after mixing. Whenever mixing insulin products...
with NPH insulin, the shorter acting insulin should be drawn into the syringe first.

**Long-Duration Insulin.** Glargine and detemir are designed as once-daily-dosing basal insulins which provide a relatively constant insulin concentration over 24 hours.\(^{22,27}\) Insulin glargine differs from regular insulin by three amino acids, resulting in a low solubility at physiologic pH. The clear solution is supplied at a pH of 4, which precipitates on subcutaneous administration. Detemir binds to albumin in the plasma, which gives it sustained action. Neither glargine nor detemir can be administered IV or mixed with other insulin products. Although detemir is recommended for dosing in the evening if being used as a once-daily dose, it stands to reason that both glargine and detemir could be administered irrespective of meals or time of day. Another long-duration insulin, insulin degludec, developed to offer an even more consistent insulin concentration throughout the day, is currently under FDA review.

**Combination Insulin Products.** A number of combination insulin products are available commercially. NPH is available in combinations of 70/30 (70% NPH and 30% regular insulin) and 50/50 (50% NPH and 50% regular insulin). Two short-acting insulin analog mixtures are also available. Humalog mix 75/25 contains 75% insulin lispro protamine suspension and 25% insulin lispro. Novolog mix 70/30 contains 70% insulin aspart protamine suspension and 30% insulin aspart. The lispro and aspart insulin protamine suspensions were developed specifically for these mixture products and are not commercially available separately.

**Insulin Pump Therapy**

Insulin pump therapy consists of a programmable infusion device that allows for basal infusion of insulin 24 hours daily (see Figure 43–1), as well as bolus administration before meals and snacks. Regular or rapid-acting insulin is delivered from a reservoir either by infusion set tubing or through a small canula. Most pump infusion sets are inserted in the abdomen, arm, or other infusion site by a small needle. Most patients prefer insertion in abdominal tissue because this site provides optimal insulin absorption. Infusion sets should be changed every 2 to 3 days to reduce the possibility of infection.

Patients use a carbohydrate-to-insulin ratio to determine how many units of insulin are required. More specifically, an individual’s ratio is calculated to determine how many units of the specific insulin being used in the pump “covers” for a certain amount of carbohydrates to be ingested at a particular meal. The 450 rule (for regular insulin) or the 500 rule (for rapid-acting insulin) is commonly used. To calculate the ratio using the 500 rule, the patient would divide 500 by his or her total daily dose of insulin. Once this ratio is determined, patients can eat more or fewer carbohydrates at a given meal and adjust the bolus dose accordingly.

In addition to mealtime boluses, correction doses based on premeal glucose readings are also used. The amount of additional insulin for the correction is based on either the 1500 rule for regular insulin or the 1800 rule for rapid-acting insulin. If using rapid-acting insulin, divide 1800 by the patient’s total daily insulin dose. The resulting value will represent the reduction in glucose (mg/dL) produced by one unit of insulin. The correction dose would be given in addition to the bolus dose needed based on the patient’s carbohydrate-to-insulin ratio and the amount of carbohydrates present in the meal he or she is about to consume.

Insulin pump therapy may be used to lower blood glucose levels in any type of DM; however, patients with T1DM are the most likely candidates to use these devices. Use of an insulin pump may improve blood glucose control, reduce wide fluctuations in blood glucose levels, and allow individuals to have more flexibility in timing and content of meals and exercise schedules.

**Noninsulin Injectable Agents**

**Glucagon-Like Peptide 1 Agonists** Exenatide, liraglutide, albiglutide, and dulaglutide are indicated for the treatment of T2DM to improve glycemic control. These agents are part of the group of drugs known as incretins (Table 43–10).\(^8\)^\(^{22,29}\)

GLP-1 agonists lower blood glucose levels by: (a) producing glucose-dependent insulin secretion; (b) reducing postmeal glucagon secretion, which decreases postmeal glucose output; (c) increasing satiety which decreases food intake; and (d) regulating gastric emptying, which allows nutrients to be absorbed into the circulation more smoothly. Typical A₁c reductions vary between GLP-1 agonists. Exenatide immediate release lowers A₁c around 0.9% (0.009; 10 mmol/mol Hgb), exenatide extended-release lowers A₁c around 1.6% (0.016; 18 mmol/mol Hgb), liraglutide reduces A₁c around 1.1% (0.011; 12 mmol/mol Hgb), and albiglutide reduces A₁c around 0.78% (0.0078; 8.8 mmol/mol Hgb).\(^8\)^\(^{30}\) GLP-1 agonists typically produce moderate weight loss of around 1 to 3 kg (2.2–6.6 lbs) depending on the drug chosen.\(^8\) Exenatide is eliminated renally and is not recommended in patients with a creatinine clearance of less than 30 mL/min (0.50 mL/s).\(^22\) No specific dose adjustments are recommended for liraglutide or albiglutide in renal impairment. An increased risk of hypoglycemia occurs when GLP-1 agonists are used in combination with a sulfonylurea or insulin.\(^8\) The main side effects of GLP-1 agonist therapy include nausea, vomiting, and diarrhea. These GI adverse effects tend to lessen over time. GLP-1 agonists have been associated with cases of acute pancreatitis. Any patient presenting with symptoms of acute pancreatitis, including abdominal pain, nausea, and vomiting, should have GLP-1 agonist therapy discontinued until pancreatitis can be ruled out. Albiglutide, liraglutide, exenatide extended-release, and dulaglutide packagings contain a black-box warning about thyroid C-cell tumors.\(^22\) They are contraindicated in patients with a personal or family history of medullary thyroid cancer and in those with a history of multiple endocrine tumors.

**Amylin** Pramlintide acetate is a synthetic analog of human amylin, which is a naturally occurring neuroendocrine peptide that is cosecreted with insulin by the β cells of the pancreas in response to food. Amylin secretion is very low or completely deficient in patients with T1DM and lower than normal in patients with T2DM who require insulin. Pramlintide slows gastric emptying without altering absorption of nutrients, suppresses glucagon secretion, and leads to a reduction in food intake by increasing satiety. By slowing gastric emptying, the normal initial postmeal spike in blood glucose is reduced.

Pramlintide is given by subcutaneous injection before meals to lower postprandial blood glucose elevations in patients with types 1 or 2 DM. Pramlintide generally results in an additional A₁c reduction of 0.4% to 0.5% (0.004–0.005; 5–6 mmol/mol Hgb) and an average weight loss of 1 to 2 kg (2.2–4.4 lb).\(^8\) Hypoglycemia, nausea, and vomiting are the most common side effects encountered with pramlintide therapy, although pramlintide itself does not produce hypoglycemia. To decrease the risk of hypoglycemia, doses of short-acting, rapid-acting, or premixed insulins should be reduced by 30% to 50% before pramlintide is initiated. Primarily, the kidneys metabolize pramlintide, but dosage adjustments in liver or kidney impairment are not required.

*Pramlintide supplied as 0.6 mg/mL in 5-mL vials. Exenatide immediate-release supplied as 250 mcg/mL, 1.2 mL for the 5-mcg prefilled pen, and 2.4 mL for the 10-mcg per dose prefilled pen. Exenatide extended-release supplied as 2 mg sterile powder plus 0.65 mL diluent in single use trays. Liraglutide supplied in 6 mg/3 mL prefilled pen, which can be dialed to the desired dose of 0.6, 1.2, or 1.8 mg. Albiglutide supplied in a 30-mg and a 50-mg single-dose pen. Dulaglutide supplied in a 0.75-mg and 1.5-mg single-dose pen and prefilled syringe.

<sup>b</sup>Generic not available in United States.

T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus
Pramlintide has the potential to delay the absorption of orally administered medications. When rapid absorption is needed for the efficacy of an agent, pramlintide should be administered 1 hour after or 3 hours before the drug. Pramlintide should not be used in patients receiving medications that alter GI motility.

A disposable pen formulation is now on the market and available as SymlinPen 60 for patients with T1DM and SymlinPen 120 for people with T2DM.

**Treatment of Concomitant Conditions**

**Cardiovascular Health**

Cardiovascular disease is the major cause of morbidity and mortality for patients with DM. Interventions targeting smoking cessation, blood pressure control, lipid management, antiplatelet therapy, and lifestyle changes (including diet and exercise) can reduce the risk of cardiovascular events and should be considered as important as glycemic control in the management of a patient with DM. All patients with a history of cardiovascular disease should be prescribed aspirin 75 to 162 mg/day as a secondary prevention strategy. For those with aspirin allergy, another antiplatelet option such as clopidogrel 75 mg/day should be used. The ADA currently recommends that antiplatelet therapy should also be considered for patients with DM and no history of heart disease if that patient’s risk of cardiovascular event is calculated to be greater than 10% over 10 years. This includes most men older than 50 years of age and most women older than 60 years of age who have at least one additional cardiovascular risk factor.

The results of a number of trials, including the Action to Control Cardiovascular Risk in Diabetes (ACCORD), Action in Diabetes and Vascular Disease (ADVANCE), and Veterans Affairs Diabetes Trial (VADT), taken together with long-term follow-up information from the UKPDS and DCCT trials, have been used to formulate conclusions regarding the effect of glucose lowering on cardiovascular health. Those conclusions are: (1) short-term (3–5 years) intensive glycemic control does not improve the risk of macrovascular complications in patients with long-standing T2DM; and (2) a decrease in macrovascular risk from improved glycemic control may take more than a decade to be realized. Because of the results of these trials, the A1c goal used for most patients with T2DM is less than 7% (0.07; 53 mmol/mol Hgb), whereas a goal of less than or equal to 6.5% (0.065; 48 mmol/mol Hgb) may be used for otherwise healthy individuals who are thought to be early in the course of their diabetes. More relaxed A1c targets may be employed for those patients who are older, have numerous medical conditions limiting their life expectancy, are at increased risk for hypoglycemia, or who have had T2DM for a long period of time.

**Dyslipidemia**

The 2013 American College of Cardiology/American Heart Association Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults recommends statin therapy be considered if a patient falls into one of four statin benefit groups. The groups are:

1. Patients with clinical atherosclerotic cardiovascular disease (ASCVD);
2. Patients with no prior history of ASCVD but a LDL level of 190 mg/dL (4.91 mmol/L) or higher;
3. Patients with diabetes and no history of clinical ASCVD who are between the ages of 40 and 75 years with a LDL level between 70 and 189 mg/dL (1.81 and 4.89 mmol/L); and
4. Patients ages 40 to 75 years with no prior history of ASCVD or diabetes who have a LDL level between 70 and 189 mg/dL (1.81 and 4.89 mmol/L) and a 10-year estimated ASCVD risk of 7.5% or higher.

Severe hypertriglyceridemia may warrant therapy with niacin, a fibrate, and/or fish oil. Although it was common practice in the past to add niacin or a fibrate onto statin therapy to augment triglyceride and HDL once LDL goals were met, cardiovascular outcome benefit has not been proven when these drugs are added to statin therapy over statin therapy alone.

Refer to Chapter 12, Dyslipidemias, for more information on managing cardiovascular risk through the optimal use of antihyperlipidemic therapies.

**Hypertension**

**KEY CONCEPT** Uncontrolled blood pressure plays a major role in the development of macrovascular events as well as microvascular complications, including retinopathy and nephropathy, in patients with DM. The ADA recommends that systolic blood pressure goals for patients with DM be individualized but generally set at less than 140 mm Hg. The diastolic blood pressure goal for patients with DM is less than 90 mm Hg. In addition, there are several general principles regarding the treatment of hypertension in diabetes patients. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers are recommended as initial therapy because of their beneficial effects on renal function. It can be expected that most patients will require more than one agent to reach blood pressure goal. Renal function and serum potassium levels should be monitored closely in all patients taking an ACE inhibitor, angiotensin II receptor blocker, and/or diuretic. ACE inhibitors and angiotensin II receptor blockers are contraindicated in patients who are pregnant and in those with bilateral renal artery stenosis.

**Patient Encounter, Part 2: Follow-Up Visit**

The patient returns a week later with results from her fasting blood work. The physician also requests a fasting glucose, A1c, and vitals at today’s visit. The results are listed below.

**VS:** BP 122/76 mm Hg, P 70 beats/min, RR 19 breaths/min, T 38°C (100°F)

A1c (today): 8.2% (0.082; 66 mmol/mol Hgb)

FPG (today): 189 mg/dL (10.5 mmol/L)

**Labs (2 days ago):** Na 136 mEq/L (136 mmol/L); K 3.6 mEq/L (3.6 mmol/L); Cl 98 mEq/L (98 mmol/L); CO2, 24 mEq/L (24 mmol/L); BUN 15 mg/dL (5.4 mmol/L); SCr 0.9 mg/dL (80 μmol/L); Glu 172 mg/dL (9.5 mmol/L)

The patient is diagnosed with type 2 diabetes. Identify the goals of treatment for this patient.

What nonpharmacologic alternatives are available for this patient for her diabetes?

What are the three general categories of pharmacologic alternatives used to lower blood glucose?

What is the most appropriate initial therapy for this patient in regards to her diabetes?

What additional interventions are recommended for this patient today?
Human Immunodeficiency Virus (HIV) and Acquired Immune Deficiency Syndrome (AIDS)

Patients with risk factors for diabetes are more likely to develop diabetes when exposed to highly active antiretroviral therapy. Universal screening of all HIV patients for diabetes is controversial, but most clinicians support screening for those with risk factors, especially if those risk factors include positive family history and central adiposity. Disturbances in glucose homeostasis are a known side effect of protease inhibitor therapy. Indinavir and ritonavir block insulin-mediated glucose disposal, causing insulin resistance, but amprenavir and atazanavir have no effect on this pathway. Indinavir also increases hepatic glucose production and release and causes insulin to lose its ability to suppress hepatic glucose production. Nelfinavir, lopinavir, and saquinavir cause a 25% reduction in β-cell function, reducing first-phase insulin release. Drug selection for treating protease inhibitor–induced hyperglycemia should address the mechanism behind the adverse effect. Protease inhibitor therapy avoidance should be considered in patients with preexisting glucose abnormalities and in those with a first-degree relative with diabetes. Metformin should be used with caution in patients taking the nucleoside reverse transcriptase inhibitors stavudine, zidovudine, and didanosine because of an increased risk for lactic acidemia.

Antipsychotic Drug Therapy

An association has been recognized between second-generation antipsychotics and the development of diabetes. Risk seems to be highest with clozapine and olanzapine, but data are conflicting for risperidone and quetiapine. Aripiprazole and ziprasidone have not, as of yet, shown an increased risk for diabetes with their use. Nutrition and physical activity counseling is recommended for all patients with mental illness who are overweight or obese, especially if they are beginning second-generation antipsychotic therapy. After therapy initiation, the patient’s weight should be assessed at weeks 4, 8, and 12 and then every 3 months. In the event of weight gain greater than or equal to 5% of the patient’s baseline weight, a therapeutic adjustment should be considered. For patients who develop worsening glycemia or dyslipidemia, an antipsychotic therapy other than clozapine or olanzapine may be considered.

Treatment of Acute Complications

Hypoglycemia

Hypoglycemia, or low blood sugar, can be defined clinically as a blood glucose level of less than or equal to 70 mg/dL (3.9 mmol/L). Individuals with DM can experience symptoms of hypoglycemia at varying blood glucose levels. Those with uncontrolled glucose can experience pseudohypoglycemia which is when symptoms of hypoglycemia occur even at normal glucose levels. Those with recent low blood glucose levels may have no symptoms even at glucose values below the hypoglycemia threshold and, therefore, patients with recurrent hypoglycemia may benefit from a period of more relaxed glycemic targets. Typical symptoms of hypoglycemia include shakiness, sweating, fatigue, hunger, headaches, and confusion. Common causes of hypoglycemia include delayed or inadequate doses of medications (eg, sulfonylureas and insulin), exercising when insulin doses are reaching peak effect, or inadequately adjusted drug therapy in patients with impaired renal or hepatic function. Patients experiencing symptoms of hypoglycemia should check their blood glucose level, consume 15 g of carbohydrate, wait 15 minutes for symptom resolution, and retest. Examples of acceptable treatments may include a small box of raisins, 4 oz (~120 mL) of orange juice, 8 oz (~240 mL) of skim milk, or three to six glucose tablets. In patients receiving an α-glucosidase inhibitor in combination with a sulfonylurea or insulin, hypoglycemia should be treated with glucose tablets or skim milk owing to the mechanism of action of the α-glucosidase inhibitors. For patients with hypoglycemia experiencing a loss of consciousness, a glucagon emergency kit should be administered by the intramuscular or subcutaneous route. It is important to contact emergency medical personnel in this particular situation. The patient should be rolled onto his or her side to prevent aspiration because many patients receiving the glucagon injection vomit.

Diabetic Ketoacidosis

Diabetic ketoacidosis is a reversible but potentially life-threatening medical emergency that results from a relative or absolute deficiency in insulin. Without insulin, the body cannot use glucose as an energy source and must obtain energy via lipolysis. This process produces ketones and leads to acidosis. Although DKA occurs frequently in young patients with T1DM on initial presentation, it can occur in adults as well. Often, precipitating factors such as infection, omission, or inadequate administration of insulin can cause DKA. Signs and symptoms develop rapidly within 1 day or so and commonly include fruity or acetone breath; nausea; vomiting; dehydration; polydipsia; polyuria; and deep, rapid breathing.

Hallmark diagnostic criteria for DKA include hyperglycemia (greater than 250 mg/dL [13.9 mmol/L]), ketosis (anion gap greater than 12 mEq/L [12 mmol/L]), and acidosis (arterial pH less than or equal to 7.3). Typical fluid deficit is 5 to 7 L or more, and major deficits of serum sodium and potassium are common. The severity of DKA depends on the magnitude of the decrease in arterial pH, serum bicarbonate levels, and the mental state rather than the magnitude of the hyperglycemia. Treatment goals of DKA consist of reversing the underlying metabolic abnormalities, rehydrating the patient, and normalizing the serum glucose. Fluid replacement with normal saline at 1 to 1.5 L/hour for the first hour is recommended to rehydrate the patient and to ensure the kidneys are perfused. Potassium and other electrolytes are supplemented as indicated by laboratory assessment. The use of sodium bicarbonate in DKA is controversial and generally only recommended when the pH is less than 7.

Hyperosmolar Hyperglycemic State

Hyperosmolar hyperglycemic state (HHS) is a life-threatening condition similar to DKA that also arises from inadequate glucose.
insulin, but HHS occurs primarily in older patients with T2DM. DKA and HHS also differ in that HHS lacks the ketonemia and acidosis associated with DKA. Patients with hyperglycemia and dehydration lasting several days to weeks are at the greatest risk of developing HHS. Infection, silent myocardial infarction, cerebrovascular accident, mesenteric ischemia, acute pancreatitis, and the use of medications that affect carbohydrate metabolism including steroids and thiazide diuretics are known precipitating causes of HHS. Two main diagnostic criteria for HHS are a plasma glucose value of greater than 600 mg/dL (33.3 mmol/L) and a serum osmolality of greater than 320 mOsm/kg (320 mmol/kg). The extreme hyperglycemia and large fluid deficits resulting from osmotic diuresis are major challenges to overcome with this condition. Similar to DKA, the treatment of HHS consists of aggressive rehydration, correction of electrolyte imbalances, and continuous insulin infusion to normalize serum glucose. Blood glucose levels should be reduced gradually to minimize the risk of cerebral edema.

### Treatment of Long-Term Complications

#### Retinopathy

Diabetic retinopathy occurs when the microvasculature that supplies blood to the retina becomes damaged. This damage permits leakage of blood components through the vessel walls. Diabetic retinopathy is the leading cause of blindness in adults 20 to 74 years of age in the United States. The risk of retinopathy is increased in patients with long-standing DM, chronic hyperglycemia, hypertension, and nephropathy. Other eye disorders, including glaucoma and cataracts, are more likely to occur in patients with diabetes as well.

The ADA recommends that patients with T2DM receive a dilated eye examination at the time of diagnosis by an ophthalmologist or optometrist. Examinations should begin within 5 years of diagnosis in adults younger than 20 years of age, and at 4 years of age in children 20 to 74 years of age in the United States.

Are this patient’s blood glucose levels within target? What pattern seems to be established?

Which classes of antidiabetic drugs act in a manner that would specifically correct the undesirable glucose pattern?

Based on the information available from this encounter and previous encounters, develop a care plan for this patient. The plan should include (a) identification and assessment of all drug-related needs and/or problems, (b) a detailed therapeutic plan to address each need and problem, and (c) monitoring parameters to assess safety and efficacy.
of diagnosis of T1DM. Once one or more normal examinations occur, the dilated eye exam is recommended to be repeated at least every two years. But, in patients with documented retinopathy, an annual dilated eye exam is recommended. Glucose and blood pressure control are the best strategies for decreasing the risk and slowing the progression of retinopathy.

### Neuropathy

Peripheral neuropathy is a possible complication of diabetes. The most common types of peripheral neuropathy include chronic sensorimotor distal peripheral neuropathy, which can cause pain, tingling, and numbness in the feet and hands, and autonomic neuropathy, which can lead to hypotension, gastroparesis, sexual dysfunction, and autonomic failure in response to hypoglycemia. Two drugs, pregabalin and duloxetine, have been approved for the relief of distal peripheral neuropathy pain. A number of other drugs are also sometimes used including venlafaxine, amitriptyline, valproate, and opioids.

### Microalbuminuria and Nephropathy

DM is a leading contributor to end-stage renal disease. Early evidence of nephropathy is the presence of albumin in the urine. Therefore, as the disease progresses, larger amounts of protein spill into the urine. The ADA recommends urine protein tests annually in T2DM patients. For patients with T1DM, annual urine protein testing should begin 5 years after the diagnosis of diabetes. The most common form of screening for protein in the urine is a random collection for measurement of the urine albumin-to-creatinine ratio. The desirable value is less than 30 mcg of albumin per milligram of creatinine (3.4 mg/mmol creatinine). The terms microalbuminuria and macroalbuminuria are being replaced by the term “persistent albuminuria,” with the level of albuminuria further defined as either being between 30 and less than 299 mcg of albumin per milligram of creatinine (3.4–34 mg/mmol creatinine; previously referred to as microalbuminuria) or greater than or equal to 300 mcg of albumin per milligram of creatinine (greater than or equal to 34 mg/mmol creatinine; previously known as macroalbuminuria).

Glycemic control and blood pressure control are primary measures for the prevention of progression of nephropathy. ACE inhibitors and angiotensin II receptor blockers prevent the progression of renal disease in patients with T2DM. Treatment of advanced nephropathy includes dialysis and kidney transplantation.

### Foot Ulcers

Lower extremity amputations are one of the most feared and disabling sequelae of long-term uncontrolled DM. A foot ulcer is an open sore that develops and penetrates to the subcutaneous tissues. Complications of the feet develop primarily as a result of peripheral vascular disease, neuropathies, and foot deformations.

Peripheral arterial disease causes ischemia to the lower limbs. This decreased blood flow deprives the tissues of oxygen and nutrients and impairs the ability of the immune system to function adequately. Symptoms of peripheral arterial disease include intermittent claudication, cold feet, pain at rest, and loss of hair on the feet and toes. Smoking cessation is the single most important treatment for peripheral arterial disease. In addition, exercising by walking to the point of pain and then resting and resuming can be a vital therapy to maintain or improve the symptoms of peripheral arterial disease. Pharmacologic intervention with antiplatelet therapy (aspirin 160–325 mg/day or clopidogrel 75 mg/day) is indicated in patients with peripheral arterial disease. For those that remain symptomatic, cilostazol 100 mg twice daily may be useful to improve blood flow and reduce the symptoms of peripheral vascular disease.

Neuropathies play a large part in the development of foot ulcers. Loss of sensation in the feet allows trauma to go unnoticed. Autonomic neuropathy can cause changes in blood flow, perspiration, skin hydration, and possibly, bone composition of the foot. Motor neuropathy can lead to muscle atrophy, resulting in weakness and changes in the shape of the foot. To prevent foot complications, the ADA recommends daily visual examination of the feet and a foot check performed at every physician visit. Sensory testing with a 10-gauge monofilament can detect areas of neuropathy. Treatment consists of glycemic control, preventing infection, debriding dead tissues, applying dressings, treating edema, and limiting ambulation. Additionally, diabetics should wear properly fitted, cushioned footwear and padded socks.

### Special Situations

#### Hospitalized Care

The NICE-SUGAR (intensive versus conventional glucose in critically ill patients) trial compared intensive (81–108 mg/dL [4.5–6.0 mmol/L]) with conventional (less than 180 mg/dL [10.0 mmol/L]) glucose control using IV insulin in intensive care unit patients. At 90 days, intensively controlled patients had an increased absolute risk of death. Significantly more hypoglycemia was observed in the intensively controlled group.

Current recommendations call for critically ill patients to be started on IV insulin therapy at a threshold of 180 mg/dL (10.0 mmol/L). A goal range of 140 to 180 mg/dL (7.8–10.0 mmol/L) is recommended for the majority of patients. More stringent goals may be considered for selected critically ill patients, but only if hypoglycemia can be avoided. Scheduled subcutaneous insulin regimens with basal, nutritional, and correction components are recommended for patients who are not critically ill. Goals of less than 140 mg/dL (7.8 mmol/L) for fasting glucose and less than 180 mg/dL (10.0 mmol/L) for random glucose are recommended for noncritically ill patients.

#### Sick Days

Patients should monitor their blood glucose levels more frequently during sick days because it is common for illness to increase blood glucose values. Patients with T1DM should check their glucose and urine for ketones every 4 hours when sick. Patients with T2DM may also need to check for ketones when their blood glucose levels are greater than 300 mg/dL (16.7 mmol/L). Patients should continue to take their medications while sick. T1DM patients may require additional insulin coverage, and some with T2DM who are currently on oral medication regimens may require insulin during an acute illness. Patients should be advised to maintain their normal caloric and carbohydrate intake while ill as well as to drink plenty of noncaloric beverages to avoid dehydration. When having difficulty eating a normal diet, patients may be advised to use nondiet beverages, sports drinks, broth, crackers, soups, and nondiet gelatins to provide normal caloric and carbohydrate intake and avoid hypoglycemia. With proper management, patients can decrease their chance of illness-induced hospitalization, particularly DKA and HHS.
Patient Encounter, Part 4: Insulin Therapy

The patient returns to the office for her annual checkup. It has been 5 years since she was first diagnosed with diabetes. Her updated information is below. Her past medical and family histories are unchanged. She states that she has been adherent to medications and lifestyle changes. She complains that she has burning and tingling constantly in both of her feet.

SH: Smokes half pack cigarettes per day for 15 years; drinks bottle of wine on the weekends; denies illicit drug use

Allergies: Sulfa and penicillin

Meds: Lisinopril 20 mg by mouth once daily; atorvastatin 20 mg by mouth once daily; fluticasone nasal spray, one spray each nostril daily if needed during allergy season; metformin 1000 mg by mouth twice daily; liraglutide 1.2 mg subcutaneously once daily; multivitamin by mouth once daily

Meal History: Has been consuming approximately 30 to 45 g of carbohydrates per meal three times a day; saturated fat is limited to 12 g/day, and sodium is 2000 mg/day

Physical Activity: Was walking 4 or 5 days per week for 30 minutes at moderate intensity but has not done so recently due to tingling in feet

VS: BP 135/82 mm Hg, P 85 beats/min, RR 20 breaths/min, T 38°C (100°F), Ht 5’3” (160 cm), Wt 155 lb (70.5 kg)

Labs: Na 139 mEq/L (139 mmol/L); K 5 mEq/L (5 mmol/L); Cl 103 mEq/L (103 mmol/L); CO₂ 23 mEq/L (23 mmol/L); BUN 16 mg/dL (5.7 mmol/L); SCr 0.9 mg/dL (80 μmol/L); FPG 180 mg/dL (10.0 mmol/L); A₁c 9.7% (0.097; 83 mmol/mol Hgb); AST 28 U/L (0.47 μKat/L); ALT 31 U/L (0.52 μKat/L)

Fasting lipid profile:
- Total cholesterol: 202 mg/dL (5.22 mmol/L)
- LDL: 108 mg/dL (2.79 mmol/L)
- HDL: 43 mg/dL (1.11 mmol/L)
- TG: 205 mg/dL (2.32 mmol/L)

What additional pharmacologic options are available for this patient to lower her blood glucose to goal?

Which insulin and starting dose would be most appropriate for this patient?

What additional medications, screenings, labs, and/or referrals are recommended for the patient at this point?

What is an important lifestyle modification this patient still needs to make?

Patient Care Process

Patient Assessment:
- Assess patient for development or progression of DM and complications (see Tables 43–4 and 43–5).
- Evaluate SMBG for glycemic control, including FPG and postprandial levels (see Table 43–6).
  - Are the blood glucose values too high or low?
  - Are there specific times of day or specific days not in control?
  - Is hypoglycemia occurring?
- Review laboratory data for attainment of goals (see Table 43–6). What goals are not being met? What tests or referrals to other health care team members are needed?
- Assess patient for quality-of-life measures such as physical, psychological, and social functioning and well-being.

Therapy Evaluation:
- Perform medication history of prescription, over-the-counter, and herbal product use.
- Are there any medication problems, including presence of adverse drug reactions, drug allergies, and drug interactions?
- If patient is already receiving treatment for DM, has he/she been adherent to recommended lifestyle modifications and drug therapies? Is the patient having difficulty affording their therapies?
- Determine if patient has prescription coverage.
- Is the patient taking medications that may affect glucose control?

Care Plan Development:
- Recommend appropriate therapy and develop a plan to assess effectiveness (see Tables 43–7, 43–9, and 43–10).
- Stress adherence to prescribed lifestyle and medication regimen.
- Provide education on diabetes, lifestyle modifications, appropriate monitoring, and drug therapy:
  - Causes of DM complications and how to prevent them.
  - How diet and exercise can affect diabetes.
  - How to perform SMBG and what to do with the results.
  - When to take medications and what to expect, including adverse effects.
  - What warning sign(s) should be reported to the physician.

Follow-up Evaluation:
- Set follow up for SMBG and tolerability/presence of adverse effects based on therapy chosen.
- Follow up A₁c every 3 months until patient reaches goal, then every 6 months. See Table 43–6 for other monitoring parameters and frequency.
OUTCOME EVALUATION

- The success of therapy for DM is measured by the ability of the patient to manage his or her disease appropriately between health care provider visits.
- Appropriate therapy necessitates adequate patient education about the disease, development of a meal plan to which patients can comply, and integration of a regular exercise program.
- Patient care plans should include a number of daily evaluations to be performed by the patient, such as examining the feet for any sores, cuts, or abrasions; checking the skin for dryness to prevent cracking and chafing; and monitoring blood glucose values as directed. Weekly appraisals of weight and blood pressure are also advised.
- Until A₁c levels are at goal, quarterly visits with the patient’s primary health care provider are recommended. Table 43–6 summarizes the specific ADA goals for therapy. The practitioner should review SMBG data and a current A₁c level for progress and address any therapeutic or educational issues.
- At a minimum, yearly laboratory evaluation of serum lipids, urinary microalbumin, and serum creatinine should be performed.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Discuss the prevalence of common thyroid disorders, including mild and overt hypothyroidism and hyperthyroidism.
2. Explain the major components of the hypothalamic–pituitary–thyroid axis and interaction among these components.
3. Discuss the relationship between serum thyroid-stimulating hormone (TSH) levels and primary thyroid disease, and the advantages for use of TSH levels over other tests such as serum T₄ (thyroxine) and T₃ (triiodothyronine) levels.
4. Identify typical signs and symptoms of hypothyroidism and the consequences of suboptimal treatment.
5. Describe clinical use of levothyroxine (LT₄) in the treatment of hypothyroidism.
6. Discuss the issues regarding LT₄ product bioequivalence and reasons for maintaining patients on the same product.
7. Describe the management of hypothyroidism and hyperthyroidism in pregnant women.
9. Discuss the pharmacotherapy of Graves disease, including advantages and disadvantages of antithyroid drugs versus radioactive iodine, adverse effects, and patient monitoring.
10. Describe the potential effects of selected drugs, including amiodarone, lithium interferon-α, and tyrosine kinase inhibitors on thyroid function.

INTRODUCTION

Thyroid disorders are common. More than 2 billion people, or 38% of the world’s population, have iodine deficiency, resulting in 74 million people with goiters. Although overt iodine deficiency is not a significant problem in developed countries, a number of common thyroid conditions exist. The most common are hypothyroidism and hyperthyroidism, which often require long-term pharmacotherapy. Undetected or improperly treated thyroid disease can result in long-term adverse sequelae, including increased mortality. It is important that clinicians are aware of the prevalence of thyroid disorders, methods of identifying thyroid disorders, and appropriate therapy. This chapter focuses on the most common pharmacologically treated thyroid disorders.

EPIDEMIOLOGY OF THYROID DISEASE

Among 4392 people 12 years of age and older in a sample representing the geographic and ethnic distribution of the US population, hypothyroidism was found in 3.7% (3.4% mild) and hyperthyroidism in 0.5%. The prevalence of hypothyroidism was higher in older age groups and in whites and Hispanics; blacks had a lower prevalence of hypothyroidism. The prevalence of hypothyroidism correlated with age. Compared with the total population, people aged 50 to 79 years had an almost twofold higher prevalence, and those aged 80 years and older had a fivefold higher prevalence. Pregnant women also had a higher prevalence of hypothyroidism. The Colorado Thyroid Health Survey assessed thyroid function in 25,862 subjects attending a health fair. Overall prevalence of an abnormal TSH level was 11.7% of the study population, with 9.4% hypothyroid (9% subclinical) and 2.2% hyperthyroid (2.1% subclinical). Of the 916 subjects taking thyroid medication, 60% were euthyroid, with an equal distribution between subclinical hypothyroidism and hyperthyroidism. The National Health and Nutrition Examination Survey (NHANES) study also found that many patients receiving thyroid medications had an abnormal TSH level. These findings imply that many patients who are receiving thyroid medications are not being managed successfully.

THYROID HORMONE PHYSIOLOGY AND BIOSYNTHESIS

The thyroid gland is the largest endocrine gland in the body, residing in the neck anterior to the trachea between the cricoid cartilage and suprasternal notch. The thyroid gland produces two biologically active hormones, thyroxine (T₄) and triiodothyronine (T₃). Thyroid hormones are essential for proper fetal growth...
and development, particularly of the central nervous system (CNS). After delivery, the primary role of thyroid hormone is in regulation of energy metabolism. These hormones can affect the function of virtually every organ in the body. **KEY CONCEPT** The parafollicular C cells of the thyroid gland produce calcitonin. The function of calcitonin and its therapeutic use are discussed in other chapters in this book.

$T_4$ and $T_3$ are produced by the organification of iodine in the thyroid gland. Iodine is actively transported into the thyroid follicular cells. This inorganic iodine is oxidized by thyroid peroxidase and covalently bound to tyrosine residues of thyroglobulin. These iodinated tyrosine residues, monoiodotyrosine and diiodotyrosine, couple to form $T_4$ and $T_3$. Eighty percent of thyroid hormone is synthesized as $T_4$ and is stored in the thyroid bound to thyroglobulin. Thyroid hormones are released from the gland when needed, primarily under the influence of TSH (thyrotropin from the anterior pituitary). $T_4$ and $T_3$ are transported in the blood by three proteins, 70% bound to thyroid-binding globulin (TBG), 15% to transthyretin (thyroid-binding prealbumin), and 15% to albumin. $T_4$ is 99.97% protein bound, and $T_3$ is 99.7% protein bound, with only the unbound or free fractions physiologically active. The high degree of protein binding results in a long half-life of these hormones: approximately 7 to 10 days for $T_4$ and 24 hours for $T_3$.

Most of the physiologic activity of thyroid hormones is from the actions of $T_4$. $T_3$ can be thought of primarily as a prohormone. Eighty percent of needed $T_3$ is derived from conversion of $T_4$ to $T_3$ in peripheral tissue under the influence of tissue deiodinases. These deiodinases allow end organs to produce the amount of $T_3$ needed to control local metabolic functions. These enzymes also catabolize $T_4$ and $T_3$ to biologically inactive metabolites.

The production and release of thyroid hormones are regulated by the hypothalamic–pituitary–thyroid axis (Figure 44–1). Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the release of TSH when there are physiologically inadequate levels of thyroid hormones. TSH promotes production and release of thyroid hormones. As circulating thyroid hormone levels rise to needed levels, negative feedback results in decreased release of TSH and TRH. Release of TRH is also inhibited by somatostatin and its analogs, and release of TRH can also be inhibited by dopamine, dopamine agonists, and high levels of glucocorticoids.

**SPECTRUM OF THYROID DISEASE**

There are two general modes of presentation for thyroid disorders: changes in the size or shape of the gland and changes in secretion of hormone from the gland. In some cases, structural changes can result in changes in hormone secretion. Thyroid nodules and goiters in euthyroid patients are common problems. Patients with a goiter who are biochemically euthyroid often require no specific pharmacotherapy unless the goiter is caused by iodine deficiency. In developing countries, iodized salt is the primary therapy in treating goiter. Thyroid nodules, seen in 4% to 7% of adults, may be malignant or may autonomously secrete thyroid hormones. A discussion of thyroid nodules is beyond the scope of this chapter; however, thyroid cancer is discussed briefly in the context of levothyroxine (LT$_3$) suppressive therapy. Refer to other resources for a more extensive review of thyroid cancer management.

Changes in hormone secretion, often due to an underlying inflammatory disorder (thyroiditis), can result in hormone deficiency or excess. Although patients with overt hypothyroidism and hyperthyroidism may have dramatic signs and symptoms, most patients have subtle signs and symptoms that progress slowly over time. The availability of sensitive and specific biochemical tests for diagnosis of thyroid hormone disorders has facilitated screening and earlier case-finding and diagnosis, including in those with mild or subclinical thyroid disorders. Screening of newborns for congenital hypothyroidism has reduced the incidence of mental retardation and neonatal hypothyroidism (cretinism) dramatically in the United States. However, congenital hypothyroidism owing to iodine deficiency remains a significant worldwide public health problem.

**PATIENT ASSESSMENT AND MONITORING**

Assessment of patients for thyroid disorders entails a history and physical examination. In many patients with mild or subclinical thyroid disease, there may be an absence of specific signs and symptoms, and physical examination findings may be normal. Various diagnostic tests can be used, including serum thyroid hormone(s), TSH, thyroid antibody levels, and imaging techniques (Table 44–1). Laboratory assessment of patients with suspected thyroid disorders must be based on the continuum of disease from subclinical or mild to overt (Figure 44–2).

**TSH Levels**

**KEY CONCEPT** In most patients with thyroid hormone disorders, measurement of a serum TSH level is adequate for initial screening and diagnosis of hypothyroidism and hyperthyroidism. Serum free thyroxine...
TSH is a highly sensitive bioassay of the thyroid axis. A twofold change in serum-free $T_4$ levels will result in a 100-fold change in TSH levels. This biologic magnification by TSH allows it to be used in early diagnosis as well as in closely titrating therapy in hypothyroidism and hyperthyroidism. In patients with primary hypothyroidism or hyperthyroidism resulting from gland dysfunction, there is an inverse relationship between the TSH level and thyroid function. High TSH signifies hypothyroidism (or iatrogenic underreplacement), and low TSH signifies hyperthyroidism (or iatrogenic overreplacement). There is controversy regarding the normal or laboratory reference ranges for TSH. NHANES showed the mean TSH level in a normal population was 1.46 mIU/L (µIU/mL) (clinical laboratories use either unit of measurement, usually expressed as mIU/L or µIU/mL), but the values were not normally distributed. Although most laboratories quote the upper limit of normal for TSH between 4 and 5 mIU/L (µIU/mL), 95% of subjects had a TSH level of between 0.5 and 2.5 mIU/L (µIU/mL). The population of subjects whose TSH level was 2.5 to 4.5 mIU/L (µIU/mL) may have had mild hypothyroidism, or the non-normal distribution may reflect different normal ranges in a heterogeneous (age, sex, race) population. The mean normal TSH appears to be higher in the elderly with no clinical evidence of hypothyroidism, and there is some evidence that normal TSH ranges are sex and ethnicity specific. The target TSH for most patients being treated for thyroid disorders is not the same as the reference range. Ideally, TSH should be the mean normal value of 1.5 mIU/L (µIU/mL) (target range, 0.5–4 mIU/L or µIU/mL). The upper limit of the target range may be higher in the elderly. Therapy may be titrated within the target TSH range to maximally improve patient signs and symptoms without causing adverse effects of overtreatment or undertreatment.

### Serum $T_4$ and $T_3$ Levels

Serum $T_4$ and $T_3$ levels are used commonly to assess thyroid function. Older screening tests of thyroid function measure total serum $T_4$ or $T_3$ levels. Because of the high degree of protein binding of these hormones, the free fraction can be altered by changes in the levels of binding proteins or the degree of protein binding. Since a number of factors can alter protein binding, these older assays are very insensitive and should no longer be used routinely even with protein-binding adjustment factors such as the free $T_4$ index. Free or unbound $T_4$ ($FT_4$) and $T_3$ ($FT_3$) assays are readily available and are more sensitive in identifying thyroid dysfunction than the older total assays. However, patients with mild hypothyroidism or hyperthyroidism have normal $FT_4$ levels despite abnormal TSH levels.

### Other Diagnostic Tests

Global tests of thyroid gland function can be performed to assess the rate of hormone synthesis. The radioactive iodine uptake (RAIU) is elevated in those with hyperthyroidism and can aid in identifying thyrotoxicosis owing to nonthyroid gland sources. Radionuclide thyroid scans are used in the evaluation of thyroid nodules. Because many thyroid disorders are autoimmune, measurement of various serum antithyroid antibodies can be performed. Antithyroid peroxidase antibodies (anti-TPOAb) and antithyroglobulin antibodies (anti-TGAb) are present in many patients with hypothyroidism. Most patients with Graves disease have TSH receptor-stimulating antibodies (TSHR-SAb) as well as elevated anti-TPOAb and antimicrosomal antibodies.

### HYPOTHYROIDISM

Hypothyroidism is the most common clinical disorder of thyroid function. It is the clinical syndrome that results from inadequate secretion of thyroid hormones from the thyroid gland. The vast majority of hypothyroid patients have primary gland failure, but occasional patients have pituitary or hypothalamic failure. Most studies define hypothyroidism based on a serum TSH
level above the upper limit of the laboratory reference range. In adults, 1.4% of women and 0.1% of men are biochemically hypothyroid. However, incidence is highly age dependent. In the Colorado Thyroid Health Study, by age 64 years, 12% of women and 5% of men were hypothyroid, and in the over 74 years age group, incidence in men approached that of women. Most epidemiologic studies of hypothyroidism in the elderly show a prevalence of 6% to 12%. There is a strong correlation between the presence of anti-TPOAb or anti-TGAb and the risk of developing hypothyroidism. In patients with subclinical hypothyroidism and positive anti-TPOAb, 5% per year will progress to overt hypothyroidism. Other risk factors for development of hypothyroidism include the postpartum state, family history of autoimmune thyroid disorders, a previous history of head and neck or thyroid surgery, head and neck irradiation, other autoimmune endocrine disorders such as type 1 diabetes and Addison disease, other nonendocrine autoimmune diseases such as celiac disease and pernicious anemia, history of treatment for hyperthyroidism, treatment with amiodarone or lithium, and an iodine-deficient diet.

### Screening for Hypothyroidism

Because prevalence of hypothyroidism is high in certain populations, screening may be useful. Screening for hypothyroidism in women older than age 35 years may be cost-effective, though some organizations recommend screening of adults after age 50 or 60 years. Others advocate a case-finding approach, defined as performing a TSH determination in patients based on risk factors or presence of signs and symptoms.

### Causes of Hypothyroidism

The most common causes of hypothyroidism are listed in Table 44–2. Up to 90% of patients with autoimmune thyroiditis (Hashimoto disease) have circulating anti-TPOAbs. The autoimmune inflammatory response results in a lymphocytic infiltration of the thyroid gland and its eventual destruction.

Iatrogenic hypothyroidism can occur after thyroid irradiation or surgery and excessive doses of antithyroid drugs. Several drugs can cause hypothyroidism, including iodine-containing drugs such as amiodarone and iodinated radiographic media, lithium, interferon-α, multikinase and tyrosine kinase inhibitors (imatinib, sunitinib, sorafenib), p-aminosalicylic acid, ethionamide, sulfonyleureas, valproic acid and other antiepileptic drugs, and aminoglutethimide. Iodine deficiency is a common worldwide cause of hypothyroidism, including congenital hypothyroidism in newborns. Patients with hypothalamic or pituitary disease often have other signs of pituitary disease, such as hypogonadism, and their TSH levels are low.

### Signs and Symptoms of Hypothyroidism

KEY CONCEPT Hypothyroidism can affect virtually any tissue or organ in the body. The most common symptoms, such as fatigue, lethargy, sleepiness, cold intolerance, and dry skin, are nonspecific and can be seen with many other disorders. The classic overt signs, such as myxedema and delayed deep tendon reflexes, are seen uncommonly now because more patients are screened or seek medical attention earlier. Patients with mild (also known as subclinical) hypothyroidism may have subtle symptoms that progress so slowly that they are not noticed easily by the patient or family. The lack of overt or specific signs and symptoms emphasizes the importance of using serum TSH level to identify patients with hypothyroidism.

### Mild (Subclinical) Hypothyroidism

Mild or subclinical hypothyroidism is present when a patient has a TSH above the upper limit of the laboratory reference range but usually below 10 mIU/L or μIU/mL, normal FT₃, and no overt hypothyroid signs and symptoms. Many of these patients have autoimmune thyroiditis and anti-TPOAbs and some will progress to overt hypothyroidism. Although patients may not express the typical symptoms of hypothyroidism, many patients do have mild, nonspecific symptoms (e.g., fatigue, cold intolerance, constipation). Recent studies have shown subclinical hypothyroidism to be a risk factor for cardiovascular mortality and to be associated with decreased myocardial contractility, decreased exercise tolerance, elevated low-density lipoprotein (LDL) cholesterol, and neuropsychiatric symptoms.
Sequelae of Hypothyroidism

Hypothyroidism is a chronic disease that may result in significant long-term sequelae. Hypercholesterolemia is associated with hypothyroidism, increasing the long-term risk of cardiovascular disease and cardiovascular mortality. Between 4% and 14% of patients with hypercholesterolemia are found to be hypothyroid. The Colorado Thyroid Health Study showed a direct correlation between degree of TSH elevation and rise in serum cholesterol. Hypothyroidism also may result in increased systemic vascular resistance, decreased cardiac output, and increased diastolic blood pressure. Hypothyroidism can cause significant neuropsychiatric problems, including a dementia-like state in the elderly that is reversible with LT₄ therapy. Maternal hypothyroidism can have dire consequences for developing fetuses. Fetuses are almost completely dependent on maternal thyroid hormones during the first trimester, a time crucial for development of the CNS. Inadequately treated maternal hypothyroidism results in increased risk of miscarriage and developmental impairment in the child.

Myxedema coma is seen in advanced hypothyroidism. These patients develop CNS depression, respiratory depression, cardiovascular instability, and fluid and electrolyte disturbances. Myxedema coma often is triggered by an underlying acute medical condition such as infection, stroke, trauma, or administration of CNS depressant drugs.

Treatment of Hypothyroidism

**KEY CONCEPT** There are three major goals in the treatment of hypothyroidism: replace the missing hormones, relieve signs and symptoms, and achieve a stable biochemical euthyroid state. Although these goals should not be difficult to achieve, 20% to 40% of treated patients are not receiving optimal pharmacotherapy.

- **Thyroid Hormone Products**

A number of thyroid hormone products are marketed in the United States (Table 44–3). These products include synthetic LT₄ and T₃, combinations of synthetic LT₄ and T₃, and animal-derived products. Despite the availability of a wide array of thyroid hormone products, it is clear that synthetic LT₄ is the treatment of choice for almost all patients with hypothyroidism. LT₄ mimics the normal physiology of the thyroid gland, which secretes mostly T₄ as a prohormone. Peripheral tissues convert T₄ to T₃, as needed based on metabolic demands. If T₃ is used to treat hypothyroidism, the peripheral tissues lose their ability to control local metabolic rates. LT₄ also has distinct pharmacokinetic advantages over T₃. With a 7- to 10-day half-life, LT₄ provides a very smooth dose-response curve with little peak and trough effect. In a small number of patients who have impairment of conversion of T₄ to T₃, addition of T₃ may be warranted. T₃, with a 24-hour half-life, provides a significant peak and trough effect, and many patients have symptoms of thyrotoxicosis after each dose is administered. The use of compounded T₃ products that have not been approved by the Food and Drug Administration (FDA) or dietary supplements marketed for “thyroid health” should be strongly discouraged. For patients who have difficulty adhering to a once-daily regimen, a once-weekly LT₄ regimen is safe and effective.

Animal-derived products such as desiccated thyroid and have various degrees of purity. These products contain both LT₄ and T₃, but the amount of T₃ is much higher (T₄:T₃ = 4:1) than what would be found in the human thyroid gland (T₄:T₃ = 14:1). With the desiccated thyroid products, there are concerns about standardizing the amount of hormone and lot-to-lot variability. Although some patients want to use desiccated thyroid because it is “natural,” the products are in no way natural for humans. With the strong evidence supporting the safety and efficacy of LT₄ in the treatment of hypothyroidism, there is no rationale for the use of these animal-derived products. Patients who are being treated with these agents should be strongly encouraged to switch to synthetic LT₄. Additionally, patients should be encouraged to not purchase thyroid hormone- or iodine-containing products from health food stores or internet sites.

Several studies have been published that evaluate use of LT₄ and T₃ combinations in ratios that mimic human physiology.

IV, intravenous; LT₄, levothyroxine; T₃, triiodothyronine; T₄, thyroxine.
A meta-analysis of randomized, controlled clinical trials comparing LT₄ and T₃ combinations with LT₄ monotherapy show no outcome benefit with combination therapy. Except in rare circumstances (e.g., patients with impaired T₃-to-T₄ conversion as evidenced by adequate LT₄ dose, continued symptoms and low FT₃ level), there is no rationale for using combinations of LT₄ and T₃ to treat hypothyroidism.

**Bioequivalence and LT₄ Product Selection**

LT₄ products have a long history of bioavailability problems. Over the years, LT₄ bioavailability has increased, so maintenance doses today are significantly lower than those seen before the early 1980s. Currently, the average bioavailability of LT₄ products is about 80%. Because of long-standing concerns about LT₄ bioequivalence and because LT₄ products had never undergone formal approval by the FDA under the 1938 Food, Drug, and Cosmetics Act, the FDA mandated that all manufacturers of LT₄ products submit an Abbreviated New Drug Application (ANDA) to keep their products on the US market after 2001. Products approved under this process would have to comply with FDA manufacturing and bioequivalence standards. This action has resulted in many changes in the United States LT market, as well as renewed interest in LT₄ bioequivalence. Since 2001, a variety of brand and generic products have been approved by the FDA. Some marketed products carry AB ratings (bioequivalence) to certain other products, using a complex AB1, AB2, AB3, and AB4 system.

For many years, there have been concerns regarding the FDA bioequivalence methodology for LT₄ products. FDA bioequivalence standards allow a -20% to +25% variance in single-dose pharmacokinetic parameters between the test and reference products. Many people believe this degree of allowed variance is not appropriate for a narrow-therapeutic-index (NTI) drug such as LT₄. Furthermore, there are unique challenges to performing bioequivalence studies with an endogenous hormone such as LT₄. Because these single-dose pharmacokinetic studies are done in healthy volunteers, the pharmacokinetic data are a combination of endogenous and exogenous LT₄. Seventy percent of the area under the curve (AUC) in these studies consists of the subjects’ endogenous T₄. Blakesley and colleagues showed the standard FDA bioequivalence methodology would rate 600-, 450-, and 400-mcg LT₄ doses as bioequivalent. This study also showed that mathematically removing the subjects’ endogenous T₄ level (baseline correction) improves the sensitivity of the analysis. Based on these data, since 2003, the FDA has required that LT₄ bioequivalence data undergo baseline correction. Although this method has improved the ability to identify large differences in LT₄ bioequivalence, small but clinically significant differences will not be identified. In 2008, the FDA adopted stricter criteria for LT₄ tablet shelf-life potency (95%-105% of stated potency vs standard 90%-110%), which may reduce the intrapatient variability seen during long-term LT₄ therapy.

More important than bioequivalence is the therapeutic equivalence of LT₄ products. Will patients have the same outcomes if bioequivalent products are used? A study by Dong and colleagues helps to answer this question. Twenty-two well-controlled hypothyroid women were randomly switched to the same dose of four different products every 6 weeks. Nonbaseline corrected bioequivalence data showed these products to be bioequivalent. However, as each product switch occurred, more of the subjects had an abnormal TSH level. By the end of the third product switch, 52% had an abnormal TSH level. This is strong evidence that LT₄ products are not therapeutically equivalent even if they are rated as bioequivalent by the FDA.

Evidence does exist that small differences in LT₄ dose can result in large changes in TSH. In one study, when the daily dose was reduced by 25 mcg, 78% had an elevated TSH level. When the daily dose was increased by 25 mcg, 55% had a low TSH level. Clearly, differences in LT₄ dose or bioavailability within the FDA-allowed variance for bioequivalent products can cause significant changes in TSH.

**Therapeutic Use of LT₄**

LT₄ replacement is indicated for patients with overt hypothyroidism. However, the need for treatment is controversial in patients with mild or subclinical disease. There are no prospective clinical trials that show an outcome benefit with treating these patients. A retrospective study from the United Kingdom showed that LT₄ therapy in patients with mild hypothyroidism reduced ischemic heart disease events in patients 70 years and younger. In patients without symptoms who have underlying heart disease, high cardiovascular risk, goiter, positive anti-TPOAb and/or are infertile or pregnant, LT₄ replacement should be considered. Patients with mild or subclinical hypothyroidism do not need to be started on the full LT₄ replacement dose because they still have some endogenous hormone production. Start these patients on 25 to 50 mcg/day and titrate every 6 to 8 weeks based on TSH levels. Over time, it is likely the LT₄ dose will need to be increased slowly as the patient’s thyroid gland loses residual function.

In patients younger than age 65 years with overt hypothyroidism, the average LT₄ replacement dose is 1.6 mcg/kg/day (use ideal body weight in obese patients). However, there is wide interpatient variability in the optimal replacement dose, so individual dose titration is necessary. If there is no history of cardiac disease, these patients may be started on the full replacement dose.

The full replacement dose in patients older than age 75 years is lower, about 1 mcg/kg/day. In the elderly, the starting dose should be 25 to 50 mcg/day, and the dose should then be titrated to the target TSH value. In patients with ischemic heart disease, start with 12.5 to 25 mcg/day and slowly titrate. If the patient develops angina or other forms of myocardial ischemia, lower the dose and titrate more slowly. At the start of therapy and with each change in dose, recheck the TSH 6 to 8-week intervals. If the TSH is not in the target range (0.5-4 mIU/L or µIU/mL), change the dose by 10% to 20% and then recheck the TSH 6 to 8 weeks later. As the dose is titrated, assess the patient’s symptoms. Many patients will improve quickly, and younger patients will feel best if the TSH is titrated to low-normal to middle-normal levels (0.5–1.5 mIU/L or µIU/mL).
Risks of Overtreatment and Undertreatment

Patients receiving LT₄ therapy who are not maintained in a euthyroid state are at risk for long-term adverse sequelae. In general, overtreatment and a suppressed TSH are more common than undertreatment with an elevated TSH. Patients with long-term overtreatment are at higher risk for atrial fibrillation and other cardiovascular morbidities, depression or mental status changes, and osteoporosis. Elderly patients being treated with LT₄ have a dose-related risk of fractures even if the TSH is not suppressed below normal values. Although studies have not defined a specific TSH target range for the elderly, these patients should receive close monitoring and dose adjustments to prevent overtreatment. Patients who are undertreated are at higher risk for hypercholesterolemia and other cardiovascular problems, depression or mental status changes, and obstetric complications.

Alterations in LT₄ Dose Requirements

A number of factors can alter LT₄ dose requirements (Table 44–4), including time of administration and drug–drug and drug–food interactions. LT₄ has the greatest and most consistent bioavailability when taken in the evening on an empty stomach. The most common cause of increased dose requirement is coadministration of LT₄ with calcium or iron supplements (including prenatal vitamins). Counsel patients that they should take the LT₄ dose at least 2 hours before or 6 hours after the calcium or iron dose. The most common cause of decreased dose requirement is aging.

### Patient Encounter 1, Part 1

A 36-year-old woman comes to the clinic complaining of fatigue, lethargy, heavy periods, dry skin, and constipation for the past 6 months. She thought it was because she was "working too hard and was not eating right," but the symptoms have not improved despite her primary care provider giving her a vitamin with iron. She noticed a 2.5-kg (5.5-lb) weight gain over the past 4 months. Her friend gave her some sertraline, but she did not take it. She takes no medications other than a hormonal contraceptive, occasional acetaminophen for headache and MiraLAX for constipation. Her vital signs and physical examination, including her most recent pelvic examination findings several months ago, are normal.

### Labs

**Serum Cholesterol:** 205 mg/dL (5.30 mmol/L; normal, less than 200 mg/dL, or 5.17 mmol/L); LDL cholesterol 96 mg/dL (2.48 mmol/L; normal less than 130 mg/dL or 3.36 mmol/L)

**TSH:** 7.8 mIU/L (μIU/mL; reference range, 0.5–4.5 mIU/L or μIU/mL)

**Free T₄:** 0.96 ng/dL (12.4 pmol/L; reference range, 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L)

**PE:**

VS: Wt 68 kg (150 lb); Ht 5’5” (165 cm); BMI 25 kg/m²

Should the patient receive LT₄ therapy? Why or why not?
If you feel treatment is indicated, what initial dose of LT₄ would you choose?
If you feel treatment is not indicated, how would you monitor the patient?
What would you tell the patient regarding the significance of her symptoms, elevated TSH level, and risk versus benefits of LT₄ therapy?

LT₄, levothyroxine; TBG, thyroxine-binding globulin.
Acting as a TSH receptor agonist, increasing the amount of thyroid hormone available for fetal growth and development.

Maternal hypothyroidism results in an increased rate of miscarriage and decreased intellectual capacity of the child. Endocrinologists recommend a TSH measurement as soon as the pregnancy is confirmed. Most hypothyroid women who become pregnant will quickly need an increased dose of LT₄, typically 20% to 50% above the prepregnancy dose. The increased dose should be maintained throughout the pregnancy, with monthly TSH monitoring to keep the TSH in the middle- to low-normal range. After delivery, the LT₄ dose usually can be reduced to prepregnancy levels, although patients with preexisting autoimmune thyroiditis may have increased postpartum dose requirements. Because prenatal vitamins contain significant amounts of calcium and iron, remind these patients to take the LT₄ dose at least 2 hours before or 6 hours after the vitamin.

**Children** Congenital hypothyroidism is uncommon in the United States, and all newborns in the United States undergo screening with a TSH level. As soon as the hypothyroid state is identified, the newborn should receive the full LT₄ replacement dose. The replacement dose of LT₄ in children is age dependent. In newborns, the usual dose is 10 to 17 mcg/kg/day. LT₄ tablets may be crushed and mixed with breast milk or formula, but it is best to administer LT₄ to infants and children on an empty stomach. Serum FT₃ levels (target, 1.6–2.2 ng/dL or 20.6–28.3 pmol/L) are used for dose titration in infants because the TSH level may not respond to treatment as it does in older children and adults. By 6 months of age, the required dose is reduced to 5 to 7 mcg/kg/day, and from ages 1 to 10 years, the dose is 3 to 6 mcg/kg/day. After age 12 years, adult doses can be given.

**Myxedema Coma** This is a life-threatening condition owing to severe, long-standing hypothyroidism and has a mortality rate of 60% to 70%. These patients are given 300 to 500 mcg LT₄ intravenously initially, using caution in patients with underlying cardiac disease. Although administration of T₃ would provide a more rapid onset of action, there is no evidence that T₃ improves outcomes in patients with myxedema coma. Historically, glucocorticoids, such as hydrocortisone 50 to 100 mg every 6 hours, are administered owing to concern about simultaneous adrenal insufficiency. Although there is no strong evidence for an outcome benefit, the use of glucocorticoids is reasonable because such treatment may be lifesaving, and the risks of a short course of corticosteroids at this dose are low. As patients improve, the LT₄ dose can be given orally in a typical full replacement dose.

**Hypothyroidism and Pregnancy** Hypothyroidism during pregnancy has a variety of maternal and fetal adverse effects. During pregnancy, β-human chorionic gonadotropin (β-hCG) acts as a TSH receptor agonist, increasing the amount of thyroid hormone available for fetal growth and development.

**Hyperthyroidism and Thyrotoxicosis**

Hyperthyroidism is much less common than hypothyroidism. Refer to the Epidemiology of Thyroid Disease section.

**Causes of Thyrotoxicosis and Hyperthyroidism**

Hyperthyroidism is related to excess thyroid hormone secreted by the thyroid gland. Thyrotoxicosis is any syndrome caused by excess thyroid hormone and can be related to excess hormone production (hyperthyroidism). The common causes of thyrotoxicosis are shown in Table 44–6. Graves disease is the most common cause of hyperthyroidism. Thyrotoxicosis in the elderly is more likely caused by toxic thyroid nodules or multinodular goiter than by Graves disease. Excessive intake of thyroid hormone may be caused by overtreatment with prescribed therapy or as a self-remedy for obesity, as thyroid hormones can be obtained easily without a prescription from health food stores or internet sources.
Patient Care Process: Hypothyroidism

Patient Assessment:
- Evaluate for signs and symptoms of hypothyroidism (see Clinical Presentation and Diagnosis of Hypothyroidism). As signs and symptoms of hypothyroidism are nonspecific, clinicians should have a high index of suspicion in higher risk patients including women and the elderly.
- Use serum TSH to identify patients with hypothyroidism (see Clinical Presentation and Diagnosis of Hypothyroidism), and check TSH in pregnant women as soon as pregnancy is determined.

Therapy Evaluation:
- If patient has been or is already receiving pharmacotherapy to treat thyroid disease, assess efficacy, safety, LT4 product received (eg, any recent changes in product) and patient adherence. Are there any significant drug interactions?
- If patient is not at desired TSH level and not on therapy, determine if pharmacotherapy is indicated.

Care Plan Development:
- Provide synthetic LT4 replacement to patients with overt hypothyroidism.
- Consider replacement therapy in patients with TSH level of greater than 4.5 but less than 10 mIU/L (μIU/mL) who have nonspecific or subtle symptoms (eg, mild fatigue, lethargy), an elevated cholesterol level, underlying heart disease, or positive anti-TPOAbs.
- Patients with mild hypothyroidism may be started at 25 to 50 mcg/day of LT4.
- Patients with overt hypothyroidism who are older than 12 and younger than 65 years and do not have cardiac disease may receive the calculated full replacement LT4 dose of 1.6 mcg/kg/day (based on ideal body weight if obese).
- Elderly patients or those with cardiac disease should be started at a lower LT4 dose (eg, 12.5–25 mcg/day).
- Provide a brand-name LT4 product, and do not allow product switches. If the product is switched, check TSH in 6 weeks and retitrate the dose.
- Provide LT4 prescriptions as microgram, not milligram, doses to avoid errors.
- Make sure patients understand importance of adherence and risks of overuse and underuse of LT4.
- In pregnant patients, expect to increase LT4 dose early in first trimester. Maintain TSH in low to middle normal range. After delivery, consider reducing LT4 dose to prepregnancy level, if appropriate.

Follow-up Evaluation:
- Measure serum TSH 6 to 8 weeks after starting or after any dose change. If TSH level is not in target range, alter dose by 10% to 20% increments. Target TSH for patients on LT4 replacement therapy for hypothyroidism is 0.5 to 2.5 mIU/L (μIU/mL). Younger patients often feel best at a TSH level in the low- to middle-normal range (ie, 0.5–1.5 mIU/L or μIU/mL).
- Check TSH every 6 to 12 months in stable patients receiving LT4 replacement.
- Monitor for drug interactions, such as LT4 absorption problems caused by calcium and iron.
- At each visit, assess for signs and symptoms of overtreatment and undertreatment.
- In pregnant patients, check TSH monthly.

hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone.

Clinical Manifestations of Thyrotoxicosis

Many of the signs and symptoms seem to be related to autonomic hyperactivity. The clinical manifestations of hyperthyroidism may be subtle and slowly progressive. Screening of patients for thyroid disease may identify patients with subclinical or mild thyrotoxicosis. Patients may seek medical attention only after a long period of thyrotoxicosis or owing to an acute complication such as atrial fibrillation. Clinical manifestations of thyrotoxicosis in the elderly may be blunted or atypical. These patients may present only with atrial fibrillation, depression, or altered mental status or cognition.

Mild (Subclinical) Hyperthyroidism

Mild (subclinical) hyperthyroidism is defined as a low TSH level with a normal FT4 level.13,26 Although there may be few or no symptoms in these patients, there are several areas of concern.14,33 Some patients progress to overt thyrotoxicosis. Patients with subclinical hyperthyroidism have been shown to experience long-term cardiovascular33,36 and bone sequelae.17 Mild hyperthyroidism appears to increase cardiovascular morbidity and mortality.18 Prolonged subclinical thyrotoxicosis speeds
Clinical Presentation and Diagnosis of Hyperthyroidism

**Symptoms**
- Nervousness
- Fatigue
- Weakness
- Increased perspiration
- Heat intolerance
- Tremor
- Hyperactivity, irritability
- Appetite change (usually increased)
- Weight change (usually weight loss)
- Menstrual disturbances (often oligomenorrhea)
- Diarrhea

**Signs**
- Hyperactivity
- Tachycardia
- Atrial fibrillation (especially in elderly adults)
- Hyperreflexia
- Warm, moist skin
- Ophthalmopathy, dermopathy (Graves disease)
- Goiter
- Muscle weakness

**Screening/Diagnosis**
- Low TSH level (less than 0.5 mIU/L or μIU/mL) signifies thyrotoxicosis.
- $FT_4$ is elevated in overt hyperthyroidism but may be normal in mild hyperthyroidism.
- Increased radioiodine uptake in the thyroid indicates increased hormone production by the thyroid gland.
- Almost all patients with Graves disease will have positive TSHR-SAbs and positive anti-TPOAbs.

Graves Disease

Graves disease is an autoimmune syndrome that includes hyperthyroidism, diffuse thyroid enlargement, exophthalmos, and other eye findings, and skin findings. The prevalence of Graves disease in the United States is approximately 0.4% in women and 0.1% in men. The peak age of incidence is 20 to 49 years, with a second peak after 80 years of age. Hyperthyroidism results from the production of TSHR-SAbs in at least 80% of patients with clinical Graves disease. These antibodies have TSH agonist activity, thereby stimulating hormone synthesis and release. These antibodies cross-react with orbital and fibroblastic tissue, resulting in ophthalmopathy and dermopathy. Although the underlying cause of Graves disease is not known, heredity seems to play a role. Subclinical Graves disease may become acutely overt in the presence of iodine excess, infection, stress, parturition, smoking, and lithium and cytokine therapy.

Several features of Graves disease are distinct from other forms of thyrotoxicosis. Clinically apparent ophthalmopathic changes are seen in 20% to 40% of patients and include exophthalmos, proptosis, chemosis, conjunctival injection, and periorbital edema. Eyelid retraction causes a typical staring or startled appearance (Figure 44-3). Patients may complain of vague eye discomfort and excess tearing. In severe cases, the eyelids are unable to close completely, resulting in corneal damage. In very severe cases, the optic nerve can be compressed, resulting in permanent vision loss. All patients with suspected or known Graves disease must be evaluated and monitored by an ophthalmologist. Treatment of the underlying hyperthyroid state often, but not always, improves the ophthalmopathy.

Dermopathy occurs in 5% to 10% of patients with Graves disease and usually is associated with severe ophthalmopathy. Skin findings include hyperpigmented, nonpitting induration of the skin, typically over the pretibial area (pretibial myxedema), the dorsa of the feet, and the shoulder areas. Clubbing of the digits (thyroid acropachy) is associated with long-standing thyrotoxicosis.

Treatment of Hyperthyroidism

Treatment of thyrotoxicosis caused by hyperthyroidism is similar regardless of the underlying cause. The goals of treating hyperthyroidism are to relieve signs and symptoms, reduce thyroid hormone production to normal levels and achieve biochemical euthyroidism, and prevent long-term adverse sequelae.

**β-Blockers**

Because many of the manifestations of hyperthyroidism appear to be mediated by the β-adrenergic system, β-adrenergic blockers are used to rapidly relieve palpitations, tremor, anxiety, and heat intolerance. Because β-blockers do not reduce the synthesis of thyroid hormones, they are used only until more specific antithyroid therapy is effective. Because nonspecific agents can impair the conversion of $T_3$ to $T_4$, propranolol and nadolol are preferred. An initial propranolol dose of 20 to 40 mg four times daily should be titrated to relieve signs (target resting heart rate less than 90 beats/min) and symptoms. β-Blockers should not be used in patients with decompensated heart failure or asthma. A more β-1 specific blocker (eg, metoprolol, atenolol) may be used when a relative contraindication to a β-blocker exists; however, when an absolute contraindication to β-blockers exists, clonidine, verapamil or diltiazem may be used for rate control.
Methods to Reduce Thyroid Hormone Synthesis

Excess production of thyroid hormone can be reduced in four ways: iodides, antithyroid drugs, radioactive iodine, and surgery.

Iodide Large doses of iodide inhibit the synthesis and release of thyroid hormones. Serum T₄ levels may be reduced within 24 hours, and the effects may last for 2 to 3 weeks. Iodides are used most commonly in Graves disease patients before surgery and to quickly reduce hormone release in patients with thyroid storm. Potassium iodide is administered either as a saturated solution (SSKI) that contains 38 mg iodide per drop or as Lugol solution, which contains 6.3 mg iodide per drop. The typical starting dose is 120 to 400 mg/day. Iodide therapy should start 7 to 14 days before surgery. Iodide should not be given before radioactive iodine treatment because the iodide will inhibit concentration of the radioactivity in the thyroid. Iodides also are used to protect the thyroid from radioactive iodine fallout after a nuclear accident or attack. Daily administration of 30 to 100 mg iodide markedly reduces thyroid gland uptake of radioactive iodine. The most frequent toxic effects with iodide therapy are hypersensitivity reactions, “iodism” (characterized by palpitations, depression, weight loss, and pustular skin eruptions), and gynecomastia.

Antithyroid Drugs The thionamide agents propylthiouracil (PTU) and methimazole (MMI) are used in the United States to treat hyperthyroidism. Carbinazole, an MMI prodrug, is used in some countries (10 mg carbinazole = 6 mg MMI). These drugs inhibit thyroid hormone synthesis by interfering with thyroid peroxidase–mediated iodination of tyrosine residues in thyroglobulin. PTU has the added effect of inhibiting the conversion of T₄ to T₃. The thionamides also have immunosuppressant effects. In patients with Graves disease treated with thionamides, TSHR-SAb levels and other immune mediators decrease over time. Both drugs are well absorbed from the gastrointestinal (GI) tract. PTU has a half-life of 1 to 2.5 hours, whereas the half-life of MMI is 6 to 9 hours.

Antithyroid drugs are used as primary therapy for Graves disease or as preparative therapy before surgery or radioactive iodine administration. The decision to use antithyroid drugs as primary therapy must be weighed against the risks and benefits of radioiodine or surgery. Patient preference must be considered. In most patients, there is no clear efficacy advantage of one thionamide over the other, but in the United States, MMI use has increased dramatically since the mid-1990s in lieu of PTU. Although PTU has the advantage of inhibiting T₄-to-T₃ conversion, MMI can be given as a single daily dose and may have a better overall safety profile, particularly less hepatotoxicity. MMI is preferred to normalize thyroid function before radioactive iodine therapy, although both thionamides increase the failure rate of radioactive iodine therapy. The usual starting dose of MMI is 10 to 20 mg/day, and the usual starting dose of PTU is 50 to 150 mg three times daily. Thyroid hormone levels drop in 2 to 3 weeks, and after 6 weeks, 90% of patients with Graves disease will be euthyroid. Thyroid function testing should be performed every 4 to 6 weeks until stable. After the patient becomes euthyroid, the antithyroid drug dose can be decreased (5–10 mg/day MMI, 100–200 mg/day PTU) to maintain the euthyroid state. Excessive doses of antithyroid drugs will result in hypothyroidism.

Remission of Graves disease occurs in 40% to 60% of patients after 1 to 2 years of therapy. Antithyroid therapy may be stopped or tapered after 12 to 24 months. Relapse usually occurs in the first 3 to 6 months after stopping antithyroid therapy. Levels of TSHR-SAb after a course of treatment may have predictive value for the risk of relapse in that antibody-positive patients almost always relapse. However, antibody-negative patients also may relapse after therapy is stopped. About 75% of women in remission who become pregnant will have a postpartum relapse. When therapy is discontinued, a therapeutic strategy should be in place in the event of relapse. Many patients will opt for radioactive iodine as a long-term solution.

Antithyroid drugs are associated with an overall low rate of adverse effects, although serious adverse effects can occur. In

2010, the FDA released a new boxed warning on severe liver injury with PTU. The warning states that PTU should only be used in patients who cannot tolerate MMI. Skin rash, arthralgias, and GI upset are seen in 5% of patients. Although the drug can be continued in the presence of a minor skin rash, the development of arthralgia warrants discontinuation. Hepatotoxicity is an uncommon but potentially serious or fatal adverse effect, occurring in 0.1% to 0.2% of patients. However, transient rises in aminotransferase enzyme levels are seen in up to 30% of patients treated with PTU. Severe hepatocellular damage can occur from PTU, whereas MMI can cause cholestatic jaundice. Antineutrophil cytoplasmic antibody (ANCA) vasculitis is another potentially serious but uncommon reaction that is more common with PTU, and patients may develop a drug-induced lupus syndrome.

**Agranulocytosis** is one of the most serious adverse effects of antithyroid drug therapy. Agranulocytosis must be distinguished from a transient decrease in white blood cell count seen in up to 12% of adults and 25% of children with Graves disease. Agranulocytosis occurs in 0.3% of patients, and the incidence may be the same with PTU and MMI therapy. Lower doses of MMI may be associated with a lower incidence of agranulocytosis. Agranulocytosis, thought to be autoimmune, almost always occurs within the first 3 months of therapy, and it occurs suddenly and unpredictably. Patients will present with fever, malaise, and a sore throat, and the absolute neutrophil count will be less than 1000/mm^3 (1 × 10^9/L). Patients may develop sepsis and die rapidly. If agranulocytosis occurs, discontinue the antithyroid drug immediately, administer broad-spectrum antibiotics if the patient is febrile, and consider administration of filgrastim. The white blood cell count should recover in 1 or 2 weeks. Patients who develop agranulocytosis should not be switched to another thionamide drug. Monitoring for agranulocytosis is controversial owing to its sudden and unpredictable nature. Most do not recommend routine monitoring of the complete blood count (CBC), although early detection could improve patient outcomes. Patients initiating thionamide therapy must be informed about the signs and symptoms of agranulocytosis and other serious side effects. Patients should be counseled to report signs and symptoms suggestive of infection, such as fever and sore throat, lasting more than 2 or 3 days, bruising, pruritic rash, jaundice, dark urine, arthralgias, abdominal pain, nausea, or fatigue.

**Radioactive Iodine** Radioactive iodine, typically ^131^I, produces thyroid ablation without surgery. ^131^I is well absorbed after oral administration. The iodine is concentrated in the thyroid gland and has a half-life of 8 days. Over a period of weeks, thyroid cells that have taken up the ^131^I begin to develop abnormalities and necrosis. Eventually, thyroid cells are destroyed, and hormone production is reduced. After a single dose, 40% to 70% of patients will be euthyroid in 6 to 8 weeks, and 80% will be cured. In most patients, hypothyroidism will develop, and long-term LT^4^ replacement will be necessary. Because ^131^I has a slow onset of action, most patients are treated initially with β-blockers and antithyroid drugs to prevent ^131^I-induced thyroid storm. MMI is the preferred agent before the administration of ^131^I. MMI is discontinued 3 to 5 days before the administration of ^131^I and is restarted 3 to 7 days later. MMI is then slowly tapered over the next 4 to 6 weeks as thyroid function normalizes. β-Blockers can be continued during ^131^I therapy. The dose of ^131^I is based on the estimated weight of the patient’s thyroid gland (typical dose, 10–15 mCi [370–555 MBq]). Radioactive iodine therapy is contraindicated during pregnancy and breastfeeding. Radioactive iodine therapy may acutely worsen Graves ophthalmopathy. Patients with prominent eye disease may be started on prednisone 40 mg/day, with the dose tapered over 2 to 3 months. Radioactive iodine also may cause a painful thyroiditis, which may necessitate anti-inflammatory therapy. No long-term carcinogenic effect of ^131^I has been demonstrated in clinical trials.

**Surgery** Subtotal thyroidecmy is indicated in patients with very large goiters and thyroid malignancies and those who do not respond or cannot tolerate other therapies. Patients must be euthyroid before surgery, and they are often administered iodide preparatively to reduce gland vascularity. The overall surgical complication rate is 2.7%. Postoperative hypothyroidism occurs in 10% of patients who undergo subtotal thyroidectomy. After thyroidectomy, serum calcium and intact parathyroid hormone levels should be monitored for early identification of postoperative hypoparathyroidism.

Postoperative administration of 1250 to 2500 mg/day of calcium and 0.5 mcg/day of calcitriol may be given and then tapered over 1 to 2 weeks if the patient does not develop hypoparathyroidism.

### Special Conditions and Populations

**Graves Disease and Pregnancy** Pregnancy may worsen or precipitate thyrotoxicosis in women with underlying Graves disease owing to the TSH agonist effect of β-hCG. Untreated maternal thyrotoxicosis may result in increased rates of miscarriage, premature delivery, eclampsia, and low-birth-weight infants. Fetal and neonatal hyperthyroidism may occur as a result of placental passage of TSHR-SABs. Because radioactive iodine is contraindicated and surgery is best avoided during pregnancy, most patients are treated with antithyroid drugs. PTU is considered the treatment of choice, particularly in the first trimester. While MMI is thought to have greater teratogenic potential versus PTU, the relative safety of these medications in pregnancy is not clear. Patients receiving prepregnancy MMI should be switched to PTU as soon as the pregnancy is confirmed. The lowest possible dose of PTU to maintain maternal euthyroidism should be used. Given the potential maternal adverse effects of PTU (eg, hepatotoxicity), it may be preferable to switch from PTU to MMI for the second and third trimesters. Antithyroid therapy in excessive doses may suppress fetal thyroid function. Although PTU and MMI are found in breast milk, nursing mothers should be switched to MMI after delivery because of the risk of hepatotoxicity from PTU in the mother and infant.

**Pediatric Hyperthyroidism** β-Blockers are administered to children who are symptomatic or have a heart rate greater than 100 beats/min. MMI is the preferred antithyroid drug therapy in children at a dose of 0.2 to 0.5 mg/kg/day. Once a euthyroid state is achieved, the MMI dose can be reduced by 50% or more to maintain euthyroidism. As in adults, antithyroid drugs are administered to children with Graves disease for 1 to 2 years. If remission does not occur in that time, long-term antithyroid drug therapy, radioactive iodine, or surgical therapy is offered. Long-term studies with radioactive iodine therapy in children show no increased risk of thyroid cancer or leukemia.

**Thyroid Storm** Thyroid storm is a life-threatening condition caused by severe thyrotoxicosis. Signs and symptoms include high fever, tachycardia, tachypnea, dehydration, delirium, coma, and GI disturbances. Thyroid storm is precipitated in a previously hyperthyroid patient by infection, trauma, surgery, radioactive iodine treatment, and sudden withdrawal from antithyroid drugs. Patients are treated with a short-acting β-blocker such as intravenous (IV) esmolol, IV or oral iodide, and large doses of...
Patient Encounter 2

A 19-year-old woman comes to the clinic stating, “I’m so jumpy and sweaty and hungry, and I’m losing weight. I think I’m losing my mind. What is wrong with me?” She first noticed these symptoms 3 months ago, and they have worsened steadily. She feels anxious for no reason and has trouble sleeping. She has noticed that her appetite has increased, although she has lost about 2 kg (4.4 lb) over the past 3 months. Sometimes she can feel her heart beating in her chest, but she denies chest pain or syncope. Her only medications are a vitamin product, occasional naproxen for headaches, and a hormonal contraceptive. She thinks that her mother had some kind of thyroid problem when she was pregnant with her.

PE:
VS: Pulse 122 beats/min, BP 106/71 mm Hg, RR 12 breaths/min, T 37.8°C (100.1°F)
HEENT: Diffusely enlarged thyroid; mild exophthalmos
CV: Tachycardic, RRR
Exts: Fine tremor
Skin: Warm, moist, and soft
ECG: Sinus tachycardia
Labs: Electrolytes, CBC normal. TSH less than 0.1 mIU/L (μIU/mL; reference range 0.5–2.5 mIU/L or μIU/mL); FT₄ 4.2 ng/dL (54.1 pmol/L; reference range 0.7–1.9 ng/dL, or 9.0–24.5 pmol/L); + TSHR-SAbs

What therapeutic options exist for this patient’s Graves disease?
What pharmacotherapy would you recommend? What if she were pregnant?
How would you initiate and titrate therapy?
What would you tell the patient regarding the cause of her signs and symptoms, significance of her abnormal thyroid function tests, and therapeutic options?

NONTHYROIDAL ILLNESS (EUTHYROID SICK SYNDROME)

A number of changes in the hypothalamic–pituitary–thyroid axis occur during acute illness. These changes are termed nonthyroidal illness or euthyroid sick syndrome. The type and degree of abnormalities depend on the severity of illness. Mild to moderate...
medical illness, surgery, or starvation causes a decrease in serum T₄ levels owing to decreased peripheral conversion of T₃ to T₂. The reduced T₄ levels do not correlate with ultimate mortality and are thought to be an adaptive response to stress. Patients with more severe illness, especially those in the intensive care unit, frequently have reduced total T₄ levels, although FT₃ levels often are normal. In critically ill patients, there is a correlation between degree of serum T₄ reduction and mortality. In most acutely ill patients who are euthyroid, TSH level is normal. However, administration of dopamine, octreotide, or high doses of glucocorticoids can reduce TSH levels. During recovery from acute illness, the TSH level may become modestly elevated to renormalize serum T₄ levels. During this time, thyroid function tests may be misinterpreted to indicate hypothyroidism. Despite the sometimes very low T₄ levels, there is no evidence that LT₄ administration has any survival benefit. Patients with possible thyroid abnormalities during acute illness should be evaluated by an endocrinologist.

**THYROID CANCER AND LT₄ SUPPRESSION**

**KEY CONCEPT** The growth and spread of thyroid carcinoma are stimulated by TSH. An important component of thyroid carcinoma management is the use of LT₄ to suppress TSH secretion. Early in therapy, patients receive the lowest LT₄ dose sufficient to fully suppress TSH to undetectable levels. Controlled trials show that suppressive LT₄ therapy reduces tumor growth and improves survival. These patients are purposefully “overtreated” with LT₄, sometimes to a fully suppressed TSH level, and rendered subclinically or mildly hyperthyroid. Postmenopausal women should receive aggressive osteoporosis therapy to prevent LT₄-induced bone loss. Other thyrotoxic complications, such as atrial fibrillation, should be monitored and managed appropriately.

**DRUG-INDUCED THYROID ABNORMALITIES**

Drugs can affect thyroid function in a number of ways. The effects of drugs on thyroid hormone protein binding, LT₄ absorption, and metabolism have been discussed previously. Several commonly used medications can alter thyroid hormone secretion.

**Amiodarone**

Amiodarone is a commonly prescribed antiarrhythmic drug that contains two iodide atoms, constituting 38% of its mass. Each 200-mg dose of amiodarone provides 75 mg of iodide. Amiodarone deiodination releases about 6 mg of free iodine daily, 20 to 40 times more than the average daily intake of iodine in the United States. Amiodarone blocks conversion of T₄ to T₃, inhibits entry of T₃ into cells, and decreases T₃ receptor binding. Amiodarone causes rapid reduction in serum T₄ levels, increases free and total T₃ levels, and increases TSH level. After 3 months of therapy, TSH levels usually return to normal, although the serum T₄ and T₃ level changes may remain. Most of these patients are euthyroid because the FT₃ levels are in the low-normal range.

Amiodarone can frequently cause thyroid abnormalities in previously euthyroid patients. In a study of amiodarone treatment of persistent atrial fibrillation, 25.8% of patients developed subclinical hypothyroidism, and 5% developed overt hypothyroidism. Hyperthyroidism occurred in 5.3%. Thyroid abnormalities, when they occurred, were seen within 6 months of initiation of amiodarone therapy in almost all patients. Amiodarone-induced hypothyroidism is more common in iodine-deficient areas of the world. Patients with underlying autoimmune thyroiditis are much more likely to develop amiodarone-induced hypothyroidism. Amiodarone-induced hypothyroidism occurs most commonly within the first year of therapy. If amiodarone cannot be discontinued, LT₄ therapy will be effective in most patients. If amiodarone can be stopped, thyroid function will return to normal in 2 to 4 months.

Amiodarone is more likely to cause thyrotoxicosis in iodine-deficient areas. Type 1 amiodarone-induced thyrotoxicosis is caused by iodine excess and typically occurs in patients with preexisting multinodular goiter or subclinical Graves disease. Type 2 amiodarone-induced thyrotoxicosis is a destructive thyroiditis that occurs in patients with no underlying thyroid disease. Amiodarone-induced thyrotoxicosis is more common in men. Because amiodarone has β-blocking activity, palpitations and tachycardia may be absent. In type 1 thyrotoxicosis, amiodarone should be discontinued. If amiodarone therapy cannot be stopped, larger doses of antithyroid drugs may be needed to control thyrotoxicosis. In type 2 thyrotoxicosis, stopping amiodarone may not be necessary because spontaneous resolution may occur. Prednisone 40 to 60 mg/day will quickly improve thyrotoxic symptoms. Prednisone may be tapered after 1 to 2 months of therapy.

**Lithium**

Lithium is associated with hypothyroidism in up to 34% of patients, and hypothyroidism may occur after years of therapy. Lithium appears to inhibit thyroid hormone synthesis and secretion. Patients with underlying autoimmune thyroiditis are more likely to develop lithium-induced hypothyroidism. Patients may require LT₄ replacement even if lithium is discontinued.

**Interferon-α**

Interferon-α causes hypothyroidism in up to 39% of patients being treated for hepatitis C infection. Patients with preexisting anti-TPOAbs are more likely to develop interferon-induced hypothyroidism. The mechanism of interferon-induced hypothyroidism is not known. If LT₄ replacement is initiated, it should be stopped after 6 months to reevaluate the need for replacement therapy.

**Tyrosine Kinase Inhibitors**

Tyrosine kinase inhibitors (TKIs) are targeted antineoplastic agents used in several types of malignancies, including thyroid cancer. Several TKIs have significant effects on thyroid function, both in previously hypothyroid patients on LT₄ replacement and in previously euthyroid patients. Imatinib has been shown to cause a fourfold increase in TSH levels in patients being treated for thyroid cancer. Sunitinib and sorafenib have been associated with primary hypothyroidism in 20% to 40% of treated patients. Some sorafenib patients developed mild hyperthyroidism before becoming hypothyroid. Patients receiving TKI therapy should have baseline and periodic thyroid function monitoring.

**OUTCOME EVALUATION**

- Desired outcomes include relieving signs and symptoms and achieving a euthyroid state.
Success of therapy for thyroid disorders must be based not only on short-term improvement of the patient’s clinical status and abnormal laboratory values but also on achievement of a long-term, stable euthyroid state. Maintaining TSH level in the normal range improves symptoms and reduces the risk of long-term complications.

Because pharmacotherapy often is lifelong, especially in patients with hypothyroidism, patients must undergo periodic monitoring to avoid long-term complications. In hypothyroid patients, such monitoring may involve simply asking the patient about signs and symptoms and a yearly measurement of TSH level.

Any change in the patient’s clinical status, such as a new pregnancy or a major change in body weight, necessitates a reevaluation of therapy. Patients at high risk for complications, such as pregnant women, the elderly, and patients with underlying cardiac disease, must be monitored more closely.

Patients should be educated and periodically reminded about the importance of adherence and long-term tight control, the need for periodic clinical and laboratory monitoring, and the importance of staying on one LT₄ product.

In hyperthyroid patients, the method of achieving desired outcomes may change over time with the use of antithyroid drugs versus radioactive iodine.

Patients who receive antithyroid drugs must be monitored for adverse drug events such as hepatotoxicity and agranulocytosis.

Patients who receive radioactive iodine must be monitored for development of hypothyroidism.

In patients with thyroid cancer, the desired outcomes with LT₄ therapy often are different from those in hypothyroid patients. LT₄ doses sufficient to suppress tumor growth may result in a suppressed TSH and mild hyperthyroidism. These patients must be monitored closely for complications of the mild hyperthyroid state, such as bone mineral loss and development of atrial fibrillation.

## REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the regulation and physiologic roles of hormones produced by the adrenal glands.
2. Recognize the clinical presentation of adrenal insufficiency.
3. Describe the pharmacologic management of acute and chronic adrenal insufficiency.
4. Recommend therapy monitoring parameters for adrenal insufficiency.
5. Recognize the clinical presentation of Cushing syndrome and the physiologic consequences of cortisol excess.
6. Describe the pharmacologic and nonpharmacologic management of Cushing syndrome.
7. Recommend strategies to prevent the development of hypercortisolism and hypocortisolism.
8. Recommend therapy monitoring parameters for Cushing syndrome.

INTRODUCTION

The adrenal glands are important in the synthesis and regulation of key human hormones. They play a crucial role in water and electrolyte homeostasis, as well as regulation of blood pressure, carbohydrate and fat metabolism, physiologic response to stress, and sexual development and differentiation. This chapter focuses on pharmacologic and nonpharmacologic management of the two most common conditions associated with adrenal gland dysfunction: glucocorticoid insufficiency (eg, Addison disease) and glucocorticoid excess (Cushing syndrome). Other adrenal disorders such as congenital adrenal hyperplasia, pheochromocytoma, hypoaldosteronism, and hyperaldosteronism are beyond the scope of this chapter.

PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY OF THE ADRENAL GLAND

The adrenal gland is located on the upper segment of the kidney. It consists of an outer cortex and an inner medulla. The adrenal medulla secretes the catecholamines epinephrine (also called adrenaline) and norepinephrine (also called noradrenaline), which are involved in the regulation of the sympathetic nervous system. The adrenal cortex consists of three histologically distinct zones: the outer zona glomerulosa, the zona fasciculata, and an innermost layer called the zona reticularis. Each zone is responsible for production of different hormones (Figure 45–1).1

The zona glomerulosa is responsible for the production of the mineralocorticoids aldosterone, 18-hydroxy-corticosterone, corticosterone, and deoxycorticosterone. Aldosterone promotes renal sodium retention and potassium excretion. Its synthesis and release are regulated by renin in response to decreased vascular volume and renal perfusion. Adrenal aldosterone production is regulated by the renin-angiotensin-aldosterone system. The zona fasciculata is the middle layer and produces the glucocorticoid hormone cortisol. Cortisol is responsible for maintaining homeostasis of carbohydrate, protein, and fat metabolism. Its secretion follows a circadian rhythm, generally beginning to rise at approximately 3 to 4 AM and peaking around 6 to 8 AM. Thereafter, cortisol levels decrease throughout the day, approach 50% of the peak value by 4 PM, and reach their nadir around midnight.2 The normal rate of cortisol production is approximately 8 to 15 mg/day.3 Cortisol plays a key role in the body’s response to stress. Its production increases markedly during physiologic stress, such as during acute illness, surgery, or trauma. In addition, certain conditions such as alcoholism, depression, anxiety disorder, obsessive-compulsive disorder, poorly controlled diabetes, morbid obesity, starvation, anorexia nervosa, and chronic renal failure are associated with increased cortisol levels. High total cortisol levels are also observed in the presence of increased cortisol binding globulin (the carrier protein for 80% of circulating cortisol molecules), which is seen in pregnancy or other high-estrogen states (eg, exogenous estrogen administration).2 Cortisol is converted in the liver to an inactive metabolite known as cortisone.

The zona reticularis produces the androgens androstenedione, dehydroepiandrosterone (DHEA), and the sulfated form of dehydroepiandrosterone (DHEA-S). Only a small amount of testosterone and estrogen is produced in the adrenal glands. Androstenedione and DHEA are converted in the periphery, largely to testosterone and estrogen.

Adrenal hormone production is controlled by the hypothalamus and pituitary. Corticotropin-releasing hormone (CRH) is secreted by the hypothalamus and stimulates secretion of adrenocorticotropic hormone (ACTH; also known as corticotropin) from the anterior pituitary. ACTH in turn stimulates the adrenal cortex to produce cortisol. When sufficient or excessive cortisol...
levels are reached, a negative feedback is exerted on the secretion of CRF and ACTH, thereby decreasing overall cortisol production. The control of adrenal androgen synthesis also follows a similar negative feedback mechanism. Figure 46–1 depicts hormonal regulation with the hypothalamic-pituitary-adrenal (HPA) axis.

ADRENAL INSUFFICIENCY
Epidemiology and Etiology

Adrenal insufficiency generally refers to the inability of the adrenal glands to produce adequate amounts of cortisol for normal physiologic functioning or in times of stress. The condition is usually classified as primary, secondary, or tertiary, depending on the etiology (Table 45–1). The estimated prevalence of primary adrenal insufficiency and secondary adrenal insufficiency is approximately 60 to 143 and 150 to 280 cases per 1 million persons, respectively. Whereas primary adrenal insufficiency is usually diagnosed in the third to fifth decade of life, secondary adrenal insufficiency is commonly detected during the sixth decade. Adrenal insufficiency is more prevalent in women than in men, with a ratio of 2.6:1. Chronic adrenal insufficiency is rare.
Table 45–1

Etiologies of Adrenal Insufficiency

Primary Adrenal Insufficiency (Addison disease)
- Autoimmune—accounts for 70%–90% of all cases of primary adrenal insufficiency
- Infectious or granulomatous diseases
- Cytomegalovirus
- Fungal (histoplasmosis, coccidioidomycosis, cryptococcosis, Blastomyces dermatitidis infection)
- HIV (human immunodeficiency virus), AIDS (acquired immunodeficiency syndrome)
- Mycobacterial, cytomegaloviral, Pneumocystic jiroveci, and Toxoplasma gondii infection
- Sarcoïdosis
- Tuberculosis
- Bilateral adrenal hemorrhage or infarction—usually due to anticoagulant therapy, coagulopathy, thromboembolic disease, or meningococcal infection. Causes acute adrenal insufficiency
- Adrenalectomy
- Adrenoleukodystrophy (in men)
- Adrenomyeloneuropathy
- Infiltrative disorders: amyloidosis, hemochromatosis
- Genetic causes
- Congenital adrenal hyperplasia
- Familial glucocorticoid deficiency and hypoplasia
- Metastatic malignancy

Secondary Adrenal Insufficiency
- Cushing syndrome
- Panhypopituitarism
- Pituitary tumor
- Transsphenoidal pituitary microsurgery
- Pituitary irradiation
- Traumatic brain injury

Tertiary Adrenal Insufficiency
- Hypothalamic dysfunction

Drug-induced (most common cause of secondary and tertiary adrenal insufficiency)
- Chronic glucocorticoid administration at supraphysiologic doses
- Steroidogenesis inhibitors
- Megestrol acetate—has glucocorticoid-like activity
- Mifepristone (RU 486)—antagonizes glucocorticoid receptors
- Tyrosine kinase inhibitors
- Inducers of CYP450 enzymes that increase cortisol metabolism (2B1, 2B2, 3A4)

CYP450, cytochrome P-450

Pathophysiology

Primary adrenal insufficiency, also known as Addison disease, occurs when the adrenal glands are unable to produce cortisol. It occurs from destruction of the adrenal cortex, usually from an autoimmune process. In general, the clinical manifestations are observed when destruction of the cortex exceeds 90%.

Key Concept

Signs and symptoms of adrenal insufficiency reflect the disturbance of normal physiologic carbohydrate, fat, and protein homeostasis caused by inadequate cortisol production and inadequate cortisol action. Primary adrenal insufficiency usually develops gradually. Patients may remain asymptomatic in the early stages with signs and symptoms present only during times of physiologic stress. Persistent signs and symptoms of hypocortisolism typically occur with disease progression. Additionally,

Clinical Presentation and Diagnosis of Chronic Adrenal Insufficiency

General
- Symptoms develop gradually, especially in the early stages, may be vague, and mimic other medical conditions.
- Patients with autoimmune adrenal insufficiency may have other autoimmune disorders such as type 1 diabetes mellitus or autoimmune thyroiditis.

Symptoms (Percent Prevalence)
- Weakness and fatigue (99%)
- Anorexia, nausea, and diarrhea (56%–90%); may range from mild to severe with vomiting and abdominal pain
- Hypoglycemia may occur
- Amenorrhea may occur
- Salt craving occurs in approximately 22% with Addison disease due to aldosterone deficiency

Signs
- Weight loss (97%)
- Hypotension (less than 110/70 mm Hg) and orthostasis (87%)
- Dehydration, hypovolemia, and hyperkalemia (in primary adrenal insufficiency only) due to aldosterone deficiency.
- Hyponatremia and hypochloridemia levels due to aldosterone deficiency. Hyponatremia can also be present in secondary insufficiency due to cortisol deficiency and increased antidiuretic hormone secretion leading to subsequent water retention.
- Increased serum blood urea nitrogen and creatinine due to dehydration.
- Hygpertigmentation of skin and mucous membranes (92%). Usually observed around creases, pressure areas, areolas, genitalia, and new scars. Dark freckles and patches of vitiligo may be present. Hyperpigmentation, due to increased ACTH levels, occurs in most patients with primary but not secondary or tertiary insufficiency.
- Personality changes (irritability and restlessness) due to cortisol deficiency.
- Loss of axillary and pubic hair in women due to decreased androgen production.
- Blood count abnormalities (normocytic, normochromic anemia, relative lymphocytosis, neutrophilia, eosinophilia) due to cortisol and androgen deficiency.

Laboratory Tests (see Table 45–2)
- Decreased basal and stress-induced cortisol levels.
- Decreased aldosterone level (in primary insufficiency only).
- Lack of increase in cortisol and aldosterone level after ACTH stimulation.

Other Diagnostic Tests
- Computed tomography (CT) scan or magnetic resonance imaging (MRI) of the adrenal glands, pituitary, and/or hypothalamus can aid in determining etiology.
- Presence of antiadrenal antibodies is suggestive of an autoimmune etiology.

</table>
| Unstimulated serum cortisol measurement | Measure serum cortisol at 6–8 AM | Serum cortisol level peaks in the early morning | Serum cortisol < 3 mcg/dL (83 nmol/L) | • Evaluate result in context of those from other test(s)  
• Can be performed in conjunction with the rapid ACTH stimulation test (measure baseline serum cortisol before administering 250 mcg of cosyntropin)  
• Used as gold standard test for diagnosing primary adrenal insufficiency  
• False negative results may occur if ACTH deficiency is of recent onset (< 1 month)  
• If measured serum cortisol concentration is low, measure plasma ACTH, aldosterone, and renin concentrations to differentiate between primary and secondary or tertiary adrenal insufficiency (see below)  
• A normal response does not exclude mild secondary adrenal insufficiency or recent onset ACTH deficiency. Additional testing (eg, insulin tolerance or metyrapone test) may be required  
• Contraindicated in patients with a seizure history, older than 60 years, or with cardiovascular or cerebrovascular disease  
| Rapid ACTH stimulation test (also called cosyntropin stimulation test) | Measure serum cortisol 30–60 minutes after administering cosyntropin 250 mcg IM or IV | Increased cortisol secretion in normal individuals in response to ACTH stimulation but not in adrenal insufficiency | Serum cortisol concentration < 18–20 mcg/dL (497–552 nmol/L) | • Distinguishes between normal individuals and patients with secondary adrenal insufficiency  
• Contraindicated in adrenal crisis and primary adrenal insufficiency  
| Insulin tolerance test (insulin-induced hypoglycemia test) | Administer insulin IV to induce hypoglycemia then measure serum cortisol during symptomatic hypoglycemia (confirm that blood glucose is < 40 mg/dL [2.2 mmol/L]) | Evaluates ability of entire HPA axis to respond to stress (hypoglycemia) | Serum cortisol concentration < 18 mcg/dL (497 nmol/L) is indicative of secondary adrenal insufficiency | • If the result of the rapid ACTH stimulation test is normal, either this or the overnight metyrapone test is still needed to evaluate for secondary adrenal insufficiency. The insulin tolerance test is considered the gold standard  
• Contraindicated in patients with a seizure history, older than 60 years, or with cardiovascular or cerebrovascular disease  
• Requires close medical supervision  
• Contraindicated in adrenal crisis and primary adrenal insufficiency  
• Distinguishes between normal individuals and patients with secondary adrenal insufficiency  
• Contraindicated in adrenal crisis and primary adrenal insufficiency  
| Overnight metyrapone test | Administer metyrapone at midnight then measure serum cortisol at 8 AM the next day | Metyrapone inhibits cortisol synthesis. Its administration leads to rise in levels of ACTH and the precursor of cortisol, 11-deoxycortisol. Patients with adrenal insufficiency do not exhibit this | Normal response is a decrease in serum cortisol to < 5 mcg/dL (138 nmol/L) and an increase in 11-deoxycortisol to > 7 mcg/dL (202 nmol/L). Response not seen in secondary adrenal insufficiency | • Evaluate result of test in combination with those from the plasma aldosterone and plasma renin tests  

(Continued)
Clinical Presentation and Diagnosis of Acute Adrenal Insufficiency (Adrenal Crisis)

**General**
- Onset of symptoms is acute and precipitated by excessive physiologic stress or abrupt discontinuation of supraphysiologic doses of chronic glucocorticoid.

**Symptoms**
- Severe weakness and fatigue
- Abdominal or flank pain

**Signs**
- Severe dehydration leading to hypotension and shock (circulatory collapse). Hypovolemia may not be responsive to intravenous (IV) hydration and may require the use of vasopressors.
- Tachycardia
- Nausea, vomiting
- Fever
- Confusion
- Hypoglycemia
- Laboratory abnormalities are similar to those observed in chronic adrenal insufficiency.

**Laboratory Tests**
- The unstimulated serum cortisol and rapid ACTH stimulation tests are useful in diagnosis (see Table 45–2). The insulin tolerance test is contraindicated due to preexisting hypoglycemia. The metyrapone test is also contraindicated since metyrapone inhibits cortisol production.

Note: Due to the life-threatening nature of this condition, empiric treatment should be started before laboratory confirmation in patients who present with the clinical picture of acute adrenal crisis.
shock. These patients are also at risk for the life-threatening consequences of an adrenal crisis. To better recognize this condition, the term ‘critical illness–related corticosteroid insufficiency’ was coined by the American College of Critical Care Medicine Task Force. Additionally, abrupt discontinuation or rapid tapering of glucocorticoids, given chronically in supraphysiologic doses, may lead to adrenal crisis. This condition results from prolonged suppression of the HPA axis and subsequent adrenal gland atrophy and hypocortisolemia. Other drugs associated with adrenal insufficiency include those that inhibit production (eg, ketoconazole) or increase metabolism (eg, the cytochrome P-450 3A4 inducer rifampin) of cortisol. Regardless of the etiology, patients experiencing an adrenal crisis require immediate glucocorticoid treatment since manifestations such as circulatory collapse can lead to life-threatening sequelae.

### Treatment and Outcome Evaluation

#### Chronic Adrenal Insufficiency

The general goals of treatment are to manage symptoms and prevent development of adrenal crisis. Long-term glucocorticoid replacement therapy may be necessary for patients with adrenal insufficiency, and mineralocorticoid replacement therapy is usually required for those with Addison disease. Glucocorticoids with sufficient mineralocorticoid activity are generally required. However, the addition of a potent mineralocorticoid such as fludrocortisone, along with adequate salt intake, is sometimes needed to prevent sodium loss, hyperkalemia, and intravascular volume depletion. Mineralocorticoid supplementation typically is not indicated for the treatment of secondary or tertiary adrenal insufficiency because aldosterone production is often unaffected. Moreover, patients with secondary or tertiary adrenal insufficiency may only require replacement therapy until the HPA axis recovers. Hydrocortisone is often prescribed because it most closely resembles endogenous cortisol with its relatively high mineralocorticoid activity and short half-life, and allows the design of regimens that simulate the normal circadian cycle. Other glucocorticoids, however, can be used.

| Table 45–3 lists the pharmacologic characteristics of commonly used glucocorticoids.11 |

Because patients with primary adrenal insufficiency can experience DHEA deficiency, DHEA replacement has also been tried. Several small clinical studies, consisting mostly of women, suggest that treatment with DHEA can improve mood and fatigue and provide a general sense of well-being.12–14 However, a recent meta-analysis of 10 studies found that DHEA use in women only slightly improved health-related quality of life and depression but did not affect anxiety or sexual well-being; it concluded that the totality of available data does not support routine supplementation with DHEA.15 The use of DHEA remains controversial and requires further study. Management strategies for chronic adrenal insufficiency are outlined below.12,14,15,16

- For the treatment of primary adrenal insufficiency (Addison disease) in adults, 15–25 mg/day of oral hydrocortisone is typically administered in two divided doses, with two-thirds of the dose given in the morning upon awakening to mimic the early morning rise in endogenous cortisol, and the remaining one-third of the dose given in the late afternoon to avoid insomnia and allow for the lowest concentration in the blood at around midnight. Hydrocortisone may also be given in three doses but this may decrease adherence. The longer-acting glucocorticoids (eg, prednisone, dexamethasone) may provide a more prolonged clinical response thereby avoiding symptom recurrence that can occur at the end of the dosing interval with short-acting agents such as hydrocortisone. Longer-acting agents also may improve adherence in some patients. Monitor the patient’s weight, blood pressure, and serum electrolytes along with symptom resolution and general well-being; adjust dosages accordingly as needed.

*S, short (ie, 8–12 hour biological t1/2); I, intermediate (ie, 12–36 hour biological t1/2); L, long (ie, 36–72 hour biological t1/2).

*bThese dose relationships apply only to oral or intravenous administration, as glucocorticoid potencies may differ greatly following intramuscular or intraarticular administration.

cThis agent is not used for glucocorticoid effects.

Patient Encounter 1, Part 1: Presentation and Medical History

A 48-year-old woman presents to the primary care clinic with complaints of fatigue and asking for a prescription for "vitamin injections." She states that she has been feeling very tired for the past year. Upon further questioning, she also complains of dizziness, especially with positional changes, and intermittent nausea, abdominal pain, and diarrhea.

PMH: Tuberculosis—completed treatment course; history of candidal vulvovaginitis; depression
FH: Mother with type 1 diabetes
SH: Denies smoking, alcohol use or illicit drug use
Current Meds: Sertraline 100 mg once daily; loperamide 2 mg as needed for diarrhea (nonprescription)

PE:
VS: Sitting BP 106/68 mm Hg, P 74 beats/min, standing BP 96/68 mm Hg, RR 14 breaths/min, Wt 130 pounds (59 kg)—5 pound (2.3 kg) loss in last 6 months, Ht 5’2″ (157 cm)

However, careful monitoring should still be performed, and the smallest effective dose used. Educate patients regarding the need for increased glucocorticoid dosage during excessive physiologic stress. In addition, administer oral fludrocortisone at a daily dose of approximately 0.05 to 0.2 mg in the morning. Monitor for resolution of hypotension, dizziness, dehydration, hypotension, and hyperkalemia; and increase the dose if needed. Conversely, consider decreasing the dose if adverse reactions from mineralocorticoid administration such as hypertension, hypokalemia, fluid retention, and other significant adverse events occur. In patients receiving hydrocortisone, it should be noted that this drug also possesses mineralocorticoid activity. All patients with Addison disease should also maintain adequate sodium intake. Lastly, although controversial, consider giving DHEA 25–50 mg/day (in the morning) to female patients who do not experience an improvement in mood and well-being even with adequate glucocorticoid and mineralocorticoid replacement. In these patients, monitor serum DHEA-S (aim for the middle range of normal levels in healthy young people) and free testosterone level.

- Patients with secondary and tertiary adrenal insufficiency are treated with oral hydrocortisone or a longer-acting glucocorticoid as described for primary adrenal insufficiency.

However, patients with secondary and tertiary adrenal insufficiency may require a lower dose. Some patients (eg, patients with drug-induced adrenal insufficiency or adrenal insufficiency following treatment for Cushing syndrome) will only require glucocorticoid replacement temporarily, which can be discontinued after recovery of the HPA axis. Monitor for progression of the underlying etiology of adrenal insufficiency. Fludrocortisone therapy is generally not needed.

- Acute Adrenal Insufficiency

  - **KEY CONCEPT** During an acute adrenal crisis, the immediate treatment goals are to correct volume depletion, manage hypoglycemia, and provide glucocorticoid replacement. Volume depletion and hypoglycemia can be corrected by giving large volumes (~ 2–3 L) of IV normal saline and 5% dextrose solution. Glucocorticoid replacement can be accomplished by administering IV hydrocortisone, starting at a dose of 100 mg every 6 hours for 24 hours, decreasing to 50 mg every 6 hours on the second day after achieving hemodynamic stability, and thereafter be tapered to a lower maintenance dose by the fourth or fifth day and fludrocortisone can be added if needed. The dose can be increased to 200 to 400 mg/day if complications. For the treatment of patients with critical illness-related corticosteroid insufficiency, see the 2008 consensus statements from the American College of Critical Care Medicine Task Force.

  - **KEY CONCEPT** Patients with known adrenal insufficiency should be educated about the need for additional glucocorticoid replacement and prompt medical attention during periods of physiologic stress. Although the dosage of glucocorticoid is generally individualized, a common recommendation is to double the maintenance dose of hydrocortisone if the patient experiences fever or undergoes invasive dental or diagnostic procedures. Patients who experience vomiting or diarrhea may not adequately absorb oral glucocorticoids and may benefit from parenteral therapy until symptoms resolve. Prior to surgery, additional glucocorticoid replacement (higher dose and parenteral route) must be given to prevent adrenal crisis. The dose and protocol varies depending

Patient Encounter 1, Part 2: Treatment

After appropriate laboratory and diagnostic tests are performed, the patient is diagnosed with Addison disease.

**How should her chronic primary adrenal insufficiency be treated?**

**What monitoring parameters (therapeutic and toxic) should be implemented?**
Patient Care Process: Adrenal Insufficiency

**Patient Assessment:**
- Evaluate for typical clinical manifestations of chronic or acute adrenal insufficiency. Clinical presentation can differentiate between chronic primary and secondary/tertiary adrenal insufficiency.
- Review medical and medication history to determine if the patient has any etiologies of adrenal insufficiency.
- Perform the rapid ACTH stimulation test to assess for presence of adrenal insufficiency (see Table 45–2).
- After diagnosis is confirmed, perform further testing to differentiate between primary, secondary, and tertiary adrenal insufficiency (see Table 45–2).

**Therapy Evaluation:**
- Determine whether patient will require mineralocorticoid replacement therapy in addition to glucocorticoid supplementation.

**Care Plan Development:**
- In patients presenting with acute adrenal crisis not previously diagnosed with adrenal insufficiency, immediate treatment with injectable hydrocortisone and IV saline and dextrose solutions should be initiated prior to confirmation of diagnosis because of the life-threatening nature of this condition. Determine and correct the underlying cause of the acute adrenal crisis (eg, infection).
- In patients with chronic adrenal insufficiency, devise a strategy to give supplemental doses of glucocorticoid when varying degrees of physiologic stress are experienced (eg, minor infection, pending surgery). Monitor patient for signs of an acute adrenal crisis and develop a plan to treat this emergency condition.
- Educate both patient and family members/caregiver regarding:
  - Causes of adrenal insufficiency, including drug-induced etiologies.
  - How to recognize clinical manifestations.
  - How to prevent an acute adrenal crisis: adhere to therapy; do not abruptly stop glucocorticoid treatment; increase glucocorticoid dose during different severity levels of physiologic stress including childhood.
  - When to self-administer parenteral glucocorticoid and seek emergency care.
  - Need to notify all health care providers of condition.
  - Wearing or carrying a medical alert (eg, bracelet, card).
  - Dietary and pharmacologic therapy, including duration of treatment and potential adverse consequences of glucocorticoid and mineralocorticoid replacement.

**Follow-Up Evaluation:**
- Monitor for adequacy of treatment and adverse reactions from glucocorticoid and/or mineralocorticoid therapy.
- Determine duration of treatment for patients with secondary and tertiary adrenal insufficiency.

**Drug-Induced Cushing Syndrome (ACTH-independent)—most common cause of Cushing syndrome**
- Prescription glucocorticoid preparations (most routes of administration)
- Nonprescription and herbal products with glucocorticoid activity (eg, nonprescription anti-itch products with hydrocortisone, herbal products with magnolia bark or those claiming to contain adrenal cortex extracts or other by-products)
- Other drugs with glucocorticoid activity (eg, megestrol acetate, medroxyprogesterone)

ACTH, adrenocorticotropic hormone or corticotropin; CRH, corticotropin-releasing hormone.

**HYPERCORTISOLISM (CUSHING SYNDROME)**

**Epidemiology and Etiology**

Cushing syndrome refers to the pathophysiologic changes associated with exposure to supraphysiologic cortisol concentrations (endogenous hypercortisolism) or pharmacologic doses of glucocorticoids (exogenous hypercortisolism). Cushing syndrome from endogenous causes is a rare condition, with an estimated incidence of two to five cases per 1 million persons per year. Patients receiving chronic supraphysiologic doses of glucocorticoids, such as those with rheumatologic disorders, are at high risk of developing Cushing syndrome.

**Pathophysiology**

Cushing syndrome can be classified as ACTH-dependent or ACTH-independent (Table 45–4). ACTH-dependent Cushing syndrome results from ACTH-secreting (or rarely CRH-secreting) adenomas. The term Cushing disease refers specifically to Cushing syndrome from an ACTH-secreting pituitary adenoma. ACTH-independent Cushing syndrome is due either to excessive cortisol secretion by the adrenal glands (independent of ACTH stimulation) or to exogenous glucocorticoid administration. The plasma ACTH concentration is elevated in ACTH-dependent conditions but not in ACTH-independent conditions because elevated cortisol concentrations suppress pituitary ACTH secretion via negative feedback. ACTH and cortisol concentrations are elevated episodically in ACTH-dependent conditions.

on the type of surgery (eg, larger doses for major surgery compared to minor surgery).
disease due to random hypersecretion of ACTH. In general, patients with Cushing syndrome due to endogenous or exogenous glucocorticoid excess present with similar clinical manifestations. However, patients with ectopic ACTH syndrome may not exhibit the typical signs and symptoms of hypercortisolism due to the acute onset nature of the underlying disease process.

Cushing disease and adrenal carcinomas cause adrenal androgen hypersecretion in high enough concentrations to result in signs of androgen excess such as acne, menstrual irregularities, and hirsutism, and cause virilization in women. Drug-induced Cushing syndrome from glucocorticoid administration occurs most commonly in patients receiving oral therapy, but other routes such as inhalation, dermal, nasal, and intraarticular have also been implicated. Over-the-counter products, including dietary supplements, should also be evaluated since they may contain corticosteroids. Drug-induced Cushing syndrome has been reported with the use of Chinese herbal products adulterated with corticosteroids. The risk of glucocorticoid-induced Cushing syndrome appears to increase with higher doses and/or longer treatment durations.

Left untreated, patients with Cushing syndrome may experience severe complications of hypercortisolism, resulting in up to a nearly four-fold increase in mortality. Mortality in patients with Cushing is mostly attributed to cardiovascular disease.

### Clinical Presentation and Diagnosis of Cushing Syndrome

#### General
- Onset of signs and symptoms range from gradual to rapid, depending on etiology.
- Differential diagnoses include diabetes mellitus and the metabolic syndrome because these conditions share several similar characteristics with Cushing syndrome (eg, obesity, hypertension, hyperlipidemia, hyperglycemia, and insulin resistance). In women, the presentations of hirsutism, menstrual abnormalities, and insulin resistance are similar to those of polycystic ovary syndrome. Cushing syndrome can be differentiated from these conditions by identifying the classic signs and symptoms described below.
- True Cushing syndrome also must be distinguished from other conditions that share some clinical presentations (as well as elevated plasma cortisol concentrations) such as depression, anxiety disorder, obsessive-compulsive disorder, alcoholism, obesity, uncontrolled diabetes, eating disorders, and physiologic stress—the so-called pseudo-Cushing states.

#### Signs and Symptoms (Percent Prevalence)

**General appearance**
- Weight gain and obesity, manifesting as truncal obesity (90%)
- Rounded and puffy face (“moon facies”) (75%)
- Dorsocervical (“buffalo hump”) and supraclavicular fat accumulation
- Hirsutism (75%)

**Skin changes from atrophy of dermis and connective tissue**
- Thin skin
- Facial plethora (70%)
- Skin striae (“stretch marks” that are usually red or purple in appearance and greater than 1 cm) (50%)—not common in patients older than 40 years of age
- Acne (35%)
- Easy bruising (40%)
- Hyperpigmentation—typically with ectopic ACTH syndrome

**Metabolic**
- Hyperglycemia that can range from impaired glucose tolerance (75%) to diabetes mellitus (20%–50%)
- Hyperlipidemia (70%)
- Polyuria (30%)
- Kidney stones (15%–50%)
- Hypokalemic alkalosis (from mineralocorticoid effect of cortisol)

**Cardiovascular**
- Hypertension (from mineralocorticoid effect of cortisol) (85%)
- Peripheral edema

**Genitourinary**
- Menstrual irregularities (typically amenorrhea) (70%)
- Erectile dysfunction (85%)

**Other**
- Psychiatric changes such as depression, emotional lability, psychosis, euphoria, anxiety, and decreased cognition (85%)
- Sleep disturbances
- Osteopenia (80%) and osteoporosis—usually affecting trabecular bone
- Linear growth impairment in children
- Proximal muscle weakness (65%)
- Avascular necrosis (more common in iatrogenic cases)
- True Cushing syndrome also must be distinguished from patients with Cushing syndrome due to endogenous or exogenous causes such as hyperplasia or adenoma.

**Differential diagnoses**
- diabetes mellitus and the metabolic syndrome shares some clinical presentations (eg, obesity, hypertension, hyperlipidemia, hyperglycemia, and insulin resistance). In women, the presentations of hirsutism, menstrual abnormalities, and insulin resistance are similar to those of polycystic ovary syndrome. 
- True Cushing syndrome also must be distinguished from other conditions that share some clinical presentations (as well as elevated plasma cortisol concentrations) such as depression, anxiety disorder, obsessive-compulsive disorder, alcoholism, obesity, uncontrolled diabetes, eating disorders, and physiologic stress—the so-called pseudo-Cushing states.

**Laboratory tests**
- Diagnosis is often complex and generally involves endocrinologists and specialized testing centers.
- Typical, a combination of two screening tests is used to establish the preliminary diagnosis.
- After the diagnosis is confirmed, additional tests (eg, midnight serum cortisol or combined dexamethasone suppression plus CRH test) can be performed to determine the etiology or rule out false positive/negative results.

**Imaging studies**
- In general, patients with Cushing syndrome due to endogenous or exogenous glucocorticoid excess present with similar clinical manifestations. However, patients with ectopic ACTH syndrome may not exhibit the typical signs and symptoms of hypercortisolism due to the acute onset nature of the underlying disease process.

#### Signs and Symptoms (Percent Prevalence)

**General appearance**
- Weight gain and obesity, manifesting as truncal obesity (90%)

Hypertension, hyperglycemia, and hyperlipidemia are common findings and can be associated with cardiac hypertrophy, atherosclerosis, and hypercoagulability. Osteopenia, osteoporosis, and increased fractures also have been reported. Prevention and management of these conditions are discussed elsewhere in this text. Children may experience linear growth retardation from reduced growth hormone secretion and inhibition of epiphyseal cartilage development in long bones.

### Treatment

The goal of treatment in patients with Cushing syndrome is reversal of hypercortisolism and management of the associated comorbidities, including the potential for long-term sequelae such as cardiac hypertrophy. Surgical resection is considered the treatment of choice for Cushing syndrome from endogenous causes if the tumor can be localized and if there are...
no contraindications. The treatment of choice for Cushing syndrome from exogenous causes is gradual discontinuation of the offending agent.

**Nonpharmacologic Therapy**

- **Transsphenoidal pituitary microsurgery** is the treatment of choice for Cushing disease. Removal of the pituitary tumor can bring about complete remission or cure in 78% to 97% of cases. HPA axis suppression associated with chronic hypercortisolism can result in prolonged adrenal insufficiency lasting for months after surgery and requiring exogenous glucocorticoid administration. Pituitary irradiation or bilateral adrenalectomy is usually reserved for patients who are not surgical candidates or for those who relapse or do not achieve complete remission following pituitary surgery. Because the response to pituitary irradiation can be delayed (several months to years), concomitant treatment with cortisol-lowering medication may be necessary. Bilateral adrenalectomy is also used for management of adrenal carcinoma and in patients with poorly controlled ectopic Cushing disease in whom the ACTH-producing lesion cannot be localized. Bilateral laparoscopic adrenalectomy achieves an immediate and total remission (nearly 100% cure rate), but these patients will require lifelong glucocorticoid and mineralocorticoid supplementation. Nelson syndrome may develop in nearly 20% to 50% of patients who undergo bilateral adrenalectomy without pituitary irradiation. This condition presumably results from persistent hypersecretion of ACTH by the intact pituitary adenoma, which continues to grow because of the loss of feedback inhibition by cortisol. Treatment of Nelson syndrome may involve pituitary irradiation or surgery.

The treatment of choice in patients with adrenal adenomas is unilateral laparoscopic adrenalectomy. These patients require glucocorticoid supplementation during and after surgery due to atrophy of the contralateral adrenal gland and suppression of the HPA axis. Glucocorticoid therapy is continued until recovery of the remaining adrenal gland is achieved. Patients with adrenal carcinomas have a poor prognosis, with a 5-year survival of 20% to 58%, because of the advanced nature of the condition (metastatic disease). Surgical resection to reduce tumor burden and size, pharmacologic therapy, or bilateral laparoscopic adrenalectomy are the treatment options commonly utilized to manage this condition.

**Pharmacologic Therapy**

- **Pharmacontherapy is indicated when the ectopic ACTH-secreting tumor cannot be localized; to control hypercortisolism to prepare for surgery; and in patients who: (1) are not surgical candidates; (2) have failed surgery or had a relapse after surgery; or (3) have Cushing disease awaiting the onset of effect of pituitary radiation.** The drugs used are classified according to their mechanism and site of action (Table 45–6). The most widely used therapeutic class is the adrenal steroidogenesis inhibitors, which can improve hypercortisolism by inhibiting enzymes involved in the biosynthesis of cortisol. Because of their potential to cause adrenal suppression, temporary glucocorticoid replacement, and in some cases mineralocorticoid supplementation, may be needed during and after treatment. **In drug-induced Cushing syndrome, discontinuation of the offending agent is the best management option.** However, abrupt withdrawal of the glucocorticoid can result in adrenal insufficiency or exacerbation of the underlying disease. Glucocorticoid doses less than 7.5 mg/day of prednisone or its equivalent for less than 3 weeks generally would not be expected to lead to suppression of the HPA axis. However, in patients receiving pharmacologic doses of glucocorticoids for prolonged periods, gradual tapering to near physiologic levels (5–7.5 mg/day of prednisone or its equivalent) should precede drug discontinuation. Administration of a short-acting glucocorticoid in the morning and use of alternate-day dosing may reduce the risk of adrenal suppression. Testing of the HPA axis may be useful in assessing adrenal reserve. In some cases, supplemental glucocorticoid administration during excessive physiologic stress may be needed for up to 1 year after glucocorticoid discontinuation.

**Table 45–7** lists strategies to prevent the development of hypercortisolism and hypocortisolism.

**Outcome Evaluation**

- **Monitor patients receiving surgical, medical, or radiation therapy for resolution of the clinical manifestations of hypercortisolism.** Symptoms often improve immediately after surgery and soon after initiation of drug therapy. However, it may take months for symptoms to resolve following radiation therapy.
- **Monitor for normalization of serum cortisol concentrations.**
- **Patient Care Process discusses additional evaluation strategies.**

---

### Patient Encounter 2

A 61-year-old man presents to a clinical pharmacist for diabetes education. He was recently diagnosed with type 2 diabetes. He also has a diagnosis of hypertension, atrial fibrillation, dyslipidemia, chronic obstructive pulmonary disease (COPD), and depression. He complains of thirst, polyuria, and fatigue. Physical exam reveals an obese (BMI 37 kg/m²) gentleman with truncal obesity, dorsocervical fat, several small bruises on abdomen and extremities, and facial plethora. His current medications include metformin, lisinopril, hydrochlorothiazide, warfarin, atorvastatin, fluticasone/salmeterol, tiotropium, albuterol, and fluoxetine. He has been treated several times this year with high-dose prednisone therapy for frequent COPD exacerbations. The clinical pharmacist suggests evaluation for possible Cushing syndrome.

**Which findings are suggestive of Cushing syndrome?**

**Aside from Cushing syndrome, what are some major differential diagnoses for clinical presentation?**

**The patient is diagnosed with drug-induced Cushing syndrome after evaluation and diagnostic testing by the endocrinologist. What patient education points should be provided?**

<tbody>
<tr>
<td><strong>Inhibitors of Adrenal Steroidogenesis</strong></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Ketoconazole&lt;sup&gt;b&lt;/sup&gt; (oral administration)</td>
<td>Inhibits several CYP450 enzymes including 17,20-lyase, 17-hydroxylase, and 11β-hydroxylase. Also inhibits cholesterol synthesis</td>
<td>Adults: 200 mg twice daily; 400–800 mg/day in two divided doses; NTE 1,200 mg/day in two to three divided doses. Extensively metabolized by liver and dosing adjustment should be considered in severe liver disease. Dosing adjustment not needed in renal disease.</td>
<td>Generally well tolerated. Symptoms of adrenal insufficiency (eg, nausea, vomiting, decreased appetite, fatigue). Gynecomastia, decreased libido, and impotence (due to inhibition of testosterone synthesis). Hepatotoxicity.</td>
<td>• Effective in a majority of causes; rapid clinical improvement seen. • Monitor efficacy with urinary cortisol. • Monitor liver transaminases for hepatotoxicity. • Useful in women with hirsutism and patients with hyperlipidemia. • Requires gastric acidity for dissolution and absorption therefore not useful in patients with achlorhydria and those taking proton pump inhibitors or round-the-clock antacids or histamine-2 receptor blockers. • Is a CYP3A4 substrate and a strong CYP3A4 inhibitor. Also has other CYP450 interaction potential. Coadministration with certain medications can lead to QT prolongation and dysrhythmia. • Used in Cushing disease, ectopic ACTH syndrome, and adrenal carcinoma. • Also used as a test to diagnose adrenal insufficiency.</td>
</tr>
<tr>
<td>Metyrapone&lt;sup&gt;b&lt;/sup&gt; (oral administration)</td>
<td>Inhibits 11β-hydroxylase. Also suppresses aldosterone synthesis</td>
<td>Adults: 750 mg/day; 500–4000 mg/day in four divided doses; NTE 6 g/day. Dosages in special populations (liver and kidney disease, elderly patients) have not been established.</td>
<td>Generally well-tolerated, Hirsutism, acne, adrenal insufficiency, GI intolerance, rash, hypokalemia, edema, hypertension.</td>
<td>• Used in Cushing disease, ectopic ACTH syndrome, and adrenal carcinoma. • Also used as a test to diagnose adrenal insufficiency.</td>
</tr>
<tr>
<td>Etomidate&lt;sup&gt;b&lt;/sup&gt; (intravenous infusion administration)</td>
<td>Inhibits 17,20-lyase, 17-hydroxylase, and 11β-hydroxylase</td>
<td>Adults: Limited clinical experience, 0.2–0.4 mg/kg/hour. Extensively metabolized in the liver to inactive metabolites. Because of changes in protein binding, dosing adjustment may be needed in kidney and liver disease.</td>
<td>Injection site pain, nausea, vomiting, myoclonus, hypotension.</td>
<td>• Is a general anesthetic. • Generally reserved for patients with more severe symptoms and in emergency settings.</td>
</tr>
<tr>
<td><strong>Adrenolytic Agent</strong></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Mitotane&lt;sup&gt;b&lt;/sup&gt; (oral administration)</td>
<td>Inhibits steroidogenesis at lower doses and is adrenolytic at higher doses. Inhibits 11β-hydroxylase and cholesterol side-chain cleavage. Reduces aldosterone synthesis.</td>
<td>Adults: for adrenal carcinoma: 2 to 6 g/day in three to four divided doses; 9–10 g/day in three to four divided doses; NTE 18–19 g/day in three to four divided doses; for other types of Cushing syndrome: 0.5 g at bedtime; 1–2 g/day; NTE 2–3 g/day, (usual/max)—give ½ the dose at bedtime to minimize nausea. Elderly patients may require a dose decrease. Primarily metabolized by the liver and dosing adjustment may be needed in liver disease.</td>
<td>GI intolerance (high incidence), fatigue, dizziness, somnolence, gynecomastia. Hyperlipidemia requiring lipid-lowering treatment. Adrenal insufficiency requiring glucocorticoid replacement therapy.</td>
<td>• FDA-approved for treatment of inoperable adrenal cortical carcinoma. Can be used in other types of Cushing syndrome. • Efficacy takes several weeks. • Lower rate of relapse when used with pituitary radiation. Also enables lower doses and therefore lower rate of adverse reactions. • Hypocortisolism (if occurs) may persist several weeks/months after discontinuation as drug is stored in fatty tissues. • Strong inducer of CYP3A4.</td>
</tr>
</tbody>
</table>
### Peripheral Glucocorticoid Antagonist

**Mifepristone (RU 486)**

*oral administration*

- **Antagonizes glucocorticoid receptors**
- **Adults**: 300 mg once daily; NTE 1200 mg once daily (but only up to 20 mg/kg/day)
- Maximum 300 mg/day with concomitant strong CYP450 inhibitors
- Do not exceed 600 mg/day in renal impairment or mild-to-moderate hepatic impairment. Do not use in severe hepatic impairment
- Nausea, fatigue, headache, hypokalemia, arthralgia, vomiting, peripheral edema, hypertension, dizziness, decreased appetite, endometrial hypertrophy, prolonged QT interval. Has abortifacient and embryotoxic properties
- **FDA-approved for control of hyperglycemia secondary to hypercortisolism in adult patients with endogenous Cushing syndrome who have type 2 diabetes mellitus or glucose intolerance and have failed surgery or are not candidates for surgery**
- **Increases cortisol and ACTH levels via antagonism of negative feedback of ACTH secretion**
- **Requires cautious use since limited clinical experiences and cannot use cortisol or ACTH levels to monitor efficacy of treatment**
- **Quicker effectiveness compared to other drug treatment options**
- **Is a CYP3A4 substrate. Also inhibits CYP3A and has other CYP450 interaction potential**

### Somatostatin Analog

**Pasireotide**

*subcutaneous injection*

- **Binds to somatostatin receptor subtype 5 overexpressed in corticotroph tumor cells resulting in inhibition of ACTH secretion**
- **Adults**: 0.6 mg or 0.9 mg twice daily; 0.3–0.9 mg twice daily; NTE 0.9 mg twice daily. Consider lower initial dose in the elderly
- Moderate hepatic impairment (Child Pugh B): initial 0.3 mg twice a day, maximum 0.6 mg twice a day. Avoid in severe hepatic impairment (Child Pugh C). No dosage adjustment needed in renal impairment
- Hyperglycemia, GI pain, nausea, diarrhea, headache, fatigue, bradycardia, QT prolongation, liver test elevations, cholelithiasis, pituitary hormone (other than ACTH) inhibition
- **FDA-approved for treatment of adult patients with Cushing disease for whom pituitary surgery is not an option or has not been curative**
- **Measure response based on 24-hour urinary free cortisol level and/or improvement in signs and symptoms**

---

*Dosing guidelines (including age ranges) and safety for children have not been definitively established.

*These medications do not have FDA-approved indications for the treatment of Cushing syndrome in either adults or children.

ACTH, adrenocorticotropic hormone or corticotropin; CYP, cytochrome P-450; FDA, Food and Drug Administration; GI, gastrointestinal; NTE, not to exceed.*
Patient Care Process: Cushing Syndrome

**Patient Assessment:**
- Perform a comprehensive examination, including a thorough medical history and history of all medications and herbal or dietary supplements.
- Determine if Cushing syndrome is drug induced.
- Establish diagnosis and etiology based on diagnostic testing.

**Therapy Evaluation:**
- Evaluate patient for appropriateness of surgery, radiation, and/or pharmacologic therapy depending on etiology.

**Care Plan Development:**
- Attempt to taper glucocorticoid if etiology is exogenous administration.
- If endogenous Cushing syndrome, determine if patient is an appropriate candidate for surgical resection of the tumor or has contraindications to surgical resection such as advanced disease (metastatic adrenal carcinoma).
- Assess response and complications associated with surgery including:
  1. Measuring plasma cortisol postsurgery to determine if the patient displays persistent hypercortisolism (surgical treatment failure) or hypocortisolism (adrenal insufficiency requiring steroid replacement therapy).
  2. In patients demonstrating hypocortisolism:
     1. Monitor for signs and symptoms of glucocorticoid withdrawal (headache, fatigue, malaise, myalgia).
- Evaluate patients with adrenal adenomas for unilateral adrenalectomy.
- Give glucocorticoid and mineralocorticoid replacement (permanently in the case of bilateral adrenalectomy).

**To Prevent Hypercortisolism and Development of Cushing Syndrome**
- Give the lowest glucocorticoid dose that will manage the disease being treated and for the shortest possible duration.
- If feasible, give glucocorticoid via administration routes that minimize systemic absorption (such as inhalation or dermal).
- If feasible, administer glucocorticoid treatment every other day (calculate the total 48-hour dose and give as a single dose of intermediate-acting glucocorticoid in the morning).
- Avoid concurrent administration of drugs that can inhibit glucocorticoid metabolism.

**To Prevent Hypocortisolism and Development of Adrenal Insufficiency or Adrenal Crisis**
- If the patient requires discontinuation from chronic treatment with supraphysiologic doses of glucocorticoid, the following discontinuation protocol can be used:
  - Gradually taper the dose to approximately 20 mg of prednisone or equivalent per day, given in the morning, and then
  - Change glucocorticoid to every other day administration, in the morning
  - Stop the glucocorticoid when the equivalent physiologic dose is reached (20 mg/day of hydrocortisone or 5–7.5 mg/day of prednisone or equivalent)
  - Understand that recovery of the HPA axis may take up to a year after glucocorticoid discontinuation during which the patient may require supplementation therapy during periods of physiologic stress.
  - Evaluate patients at risk for adrenal insufficiency as a result of treatment(s) of Cushing syndrome and initiate glucocorticoid and mineralocorticoid replacement therapy as appropriate.
  - Avoid concurrent administration of drugs that can induce glucocorticoid metabolism.
  - Educate patients about:
    1. The need for replacement or supplemental glucocorticoid and mineralocorticoid therapy.
    2. How to administer parenteral glucocorticoid if unable to immediately access medical care during an emergency.
    3. Need to wear or carry medical identification regarding condition (eg, card, bracelet).

**Table 45–7**

**Principles of Glucocorticoid Administration to Avoid Hypercortisolism or Hypocortisolism**

**To Prevent Hypercortisolism and Development of Cushing Syndrome**
- Give the lowest glucocorticoid dose that will manage the disease being treated and for the shortest possible duration.
- If feasible, give glucocorticoid via administration routes that minimize systemic absorption (such as inhalation or dermal).
- If feasible, administer glucocorticoid treatment every other day (calculate the total 48-hour dose and give as a single dose of intermediate-acting glucocorticoid in the morning).
- Avoid concurrent administration of drugs that can inhibit glucocorticoid metabolism.

**To Prevent Hypocortisolism and Development of Adrenal Insufficiency or Adrenal Crisis**
- If the patient requires discontinuation from chronic treatment with supraphysiologic doses of glucocorticoid, the following discontinuation protocol can be used:
  - Gradually taper the dose to approximately 20 mg of prednisone or equivalent per day, given in the morning, and then
  - Change glucocorticoid to every other day administration, in the morning
  - Stop the glucocorticoid when the equivalent physiologic dose is reached (20 mg/day of hydrocortisone or 5–7.5 mg/day of prednisone or equivalent)
  - Understand that recovery of the HPA axis may take up to a year after glucocorticoid discontinuation during which the patient may require supplementation therapy during periods of physiologic stress.
  - Evaluate patients at risk for adrenal insufficiency as a result of treatment(s) of Cushing syndrome and initiate glucocorticoid and mineralocorticoid replacement therapy as appropriate.
  - Avoid concurrent administration of drugs that can induce glucocorticoid metabolism.
  - Educate patients about:
    1. The need for replacement or supplemental glucocorticoid and mineralocorticoid therapy.
    2. How to administer parenteral glucocorticoid if unable to immediately access medical care during an emergency.
    3. Need to wear or carry medical identification regarding condition (eg, card, bracelet).

HPA, hypothalamic-pituitary-adrenal
Patient Care Process: Cushing Syndrome (Continued)

- How to reduce the modifiable cardiovascular and metabolic complications
- Advantages and disadvantages of potential treatment options including possible adverse consequences
- Need for glucocorticoid and mineralocorticoid replacement after treatment, if appropriate
- Importance of adherence to therapy

Follow-Up Evaluation:
- Monitor for response to therapy, need for dose adjustments, and presence of adverse drug reactions.
- Once disease control is achieved, continue to monitor biochemical markers and patient for development of complications of Cushing syndrome, as relapse may occur.

Abbreviation Introduced in This Chapter

- ACTH: Adrenocorticotropic hormone or corticotropin
- AIDS: Acquired immunodeficiency syndrome
- BUN: Blood urea nitrogen
- CRH: Corticotropin-releasing hormone
- COPD: Chronic obstructive pulmonary disease
- CT: Computed tomography
- CYP450: Cytochrome P-450
- DHEA: Dehydroepiandrosterone
- DST: Dexamethasone suppression test
- FDA: Food and Drug Administration
- GI: Gastrointestinal
- HIV: Human immunodeficiency virus
- HPA: Hypothalamic-pituitary-adrenal
- HPLC: High performance liquid chromatography
- IM: Intramuscular
- IV: Intravenous or intravenously
- MRI: Magnetic resonance imaging

REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:
1. List the mediators and primary effects of pituitary hormones.
2. Identify clinical features of patients with acromegaly.
3. Discuss the role of surgery and radiation therapy for patients with acromegaly.
4. Select appropriate pharmacotherapy for patients with acromegaly based on patient-specific factors.
5. Identify clinical features of children and adults with growth hormone (GH) deficiency and select appropriate pharmacotherapy for these patients.
6. Recommend monitoring parameters necessary to assess therapeutic outcomes and adverse effects in patients receiving GH therapy.
7. List common etiologies of hyperprolactinemia.
8. Identify clinical features of patients with hyperprolactinemia.
9. Select appropriate pharmacologic and nonpharmacologic treatments for patients with hyperprolactinemia based on patient-specific factors.

PHYSIOLOGY OF THE PITUITARY GLAND

The pituitary, referred to as the “master gland,” is a small endocrine gland located at the base of the brain and is responsible for the regulation of many other endocrine glands and body systems. Growth, development, metabolism, reproduction, and stress homeostasis are among the functions influenced by the pituitary. Functionally, the gland consists of two distinct sections: the anterior pituitary lobe and the posterior pituitary lobe. The pituitary receives neural and hormonal input from the inferior hypothalamus via blood vessels and neurons.

The posterior pituitary is innervated by nervous stimulation from the hypothalamus, resulting in the release of specific hormones to exert direct tissue effects. The hypothalamus synthesizes two hormones, oxytocin and vasopressin. These hormones are stored and released from the posterior pituitary lobe. The anterior pituitary lobe is under the control of several releasing and inhibiting hormones secreted from the hypothalamus via a portal vein system. It synthesizes and secretes six major hormones.

Figure 46–1 summarizes the physiologic mediators and effects of each of these hormones.

Hormonal Feedback Regulatory Systems

The hypothalamus is responsible for the synthesis and release of hormones that regulate the pituitary gland. Stimulation or inhibition of the pituitary hormones elicits a specific cascade of responses in peripheral target glands. In response, these glands secrete hormones that exert a negative feedback on other hormones in the hypothalamic–pituitary axis (see Figure 46–1). This negative feedback serves to maintain body system homeostasis.

In general, high circulating hormone concentrations inhibit the release of hypothalamic and anterior pituitary hormones.

Damage and destruction of the pituitary gland may result in secondary hypothyroidism, hypogonadism, adrenal insufficiency, growth hormone (GH) deficiency, hypoprolactinemia, or panhypopituitarism. A tumor (adenoma) located in the pituitary gland may result in excess secretion of a hormone or may physically compress the gland and suppress adequate hormone release. The type, location, and size of a pituitary tumor often determine a patient’s clinical presentation. This chapter discusses the pathophysiology and role of pharmacotherapy in the treatment of acromegaly, GH deficiency, and hyperprolactinemia. The following hormones are discussed elsewhere in this textbook: adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), antidiuretic hormone (or vasopressin; ADH), and oxytocin.

GROWTH HORMONE (SOMATOTROPIN)

Somatotropin or GH, the most abundant hormone produced by the anterior pituitary lobe, is regulated primarily by the hypothalamic–pituitary axis. The hypothalamus releases growth hormone–releasing hormone (GHRH) to stimulate GH synthesis and secretion, whereas somatostatin inhibits it. Release of GH into the circulation stimulates the liver and other peripheral target tissues to produce insulin-like growth factors (IGFs). These IGFs are the peripheral GH targets. There are two types of IGFs, IGF-1 and IGF-2. IGF-1 is responsible for growth of bone and other tissues, whereas IGF-2 is primarily responsible for regulating fetal growth. High concentrations of IGF-1 inhibit
FIGURE 46–1. Hypothalamic–pituitary–target-organ axis. The hypothalamic hormones regulate the biosynthesis and release of eight pituitary hormones. Stimulation of each of these pituitary hormones produces and releases trophic hormones from their associated target organs to exert their principal effects. These trophic hormones regulate the activity of endocrine glands. Subsequently, increased serum concentration of the tropic hormones released from the target organs can inhibit both the hypothalamus and the anterior pituitary gland to maintain homeostasis (negative feedback). Inhibin is produced by the testes in men and the ovaries in women during pregnancy. Inhibin directly inhibits pituitary production of follicle-stimulating hormone (FSH) through a negative feedback mechanism. Melanocyte-stimulating hormone (MSH) produced by the anterior pituitary is not illustrated in the figure. (–), inhibit; (+), stimulate; ACTH, adrenocorticotropic hormone (corticotropin); ADH, antidiuretic hormone (vasopressin); CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GABA, γ-aminobutyric acid; GH, growth hormone (somatotropin); GHIH, growth hormone–inhibiting hormone (somatostatin); GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-I, insulin-like growth factor-I; LH, luteinizing hormone; LHRH, luteinizing hormone–releasing hormone; PRH, prolactin-releasing hormone; T3, triiodothyronine; T4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone (thyrotropin).

GH secretion through somatostatin, thereby inhibiting GHRH secretion at the hypothalamus. The hypothalamus also may stimulate the release of somatostatin to inhibit GH secretion. The effects of IGF-I in peripheral tissues are both GH dependent and GH independent. GH is an anabolic hormone with direct “anti-insulin” metabolic effects. By stimulating protein synthesis and shifting the body’s energy source from carbohydrates to fats, GH promotes a diabetic state (Table 46–1). GH controls somatic growth and has a critical role in the development of normal skeletal muscle, myocardial muscle, and bone.

In healthy individuals, GH is secreted in a pulsatile manner with several short bursts occurring mostly during the night. The amount of GH secretion fluctuates throughout a person’s lifetime. Secretion of GH is lowest during infancy, increases during childhood, peaks during adolescence, and then declines gradually during the middle years. These changes are parallel to an age-related decline in lean muscle mass and bone mineral density.

**Growth Hormone Excess**

**Epidemiology and Etiology**

Acromegaly affects both genders equally, and the average age of presentation is 44 years. Approximately 40 to 125 people per 1 million are affected, with an estimated annual incidence of three to four cases per 1 million people. In more than 95% of cases, overproduction of GH is caused by a benign pituitary adenoma, whereas malignant adenomas are rare. Most pituitary adenomas occur spontaneously as a result of a sporadic genetic mutation acquired during life. Depending on tumor size, pituitary adenomas...
are classified as: (a) microadenomas if they are 10 mm or less in diameter; or (b) macroadenomas if they are greater than 10 mm. Although these tumors can produce GH, they more commonly secrete GHRH, resulting in excessive GH and IGF-I production.

**Pathophysiology**

Acromegaly is a rare disorder that manifests gradually over time and typically occurs after fusion of the epiphyses (growth plates) of the long bones. The facial and hand features of an acromegalic patient are depicted in Figures 46–2 and 46–3. Gigantism refers to GH excess that occurs during childhood before epiphyseal closure and results in excessive linear growth. Because the signs and symptoms of acromegaly are insidious, diagnosis of this disorder is often delayed for up to 10 years after the initial presentation of symptoms. Therefore, it is important for practitioners to be vigilant in identifying this disease in the early stages.

Diagnosis of acromegaly is based on both clinical and biochemical findings. Because GH fluctuates throughout the day, a single random measurement is never a reliable diagnostic tool to evaluate GH excess. GH is suppressed after administration of a 75-g oral glucose challenge because postprandial hyperglycemia inhibits secretion of GH. Therefore, measurement of serum GH secretion in response to an oral glucose tolerance test (OGTT) is the primary biochemical test for diagnosing acromegaly. If the nadir GH concentration is greater than 0.4 ng/mL (0.4 mcg/L; 18 pmol/L) during the test or the random GH concentration is greater than 1 ng/mL (1 mcg/L; 45 pmol/L), the patient is diagnosed with acromegaly. In addition to clinical presentation, an elevated IGF-I serum concentration helps to confirm the diagnosis. IGF-I concentrations are often represented as age- and sex-matched population values. They are relatively stable and correlate positively with mean GH concentrations, thus making elevations in IGF-I concentrations an ideal and reliable biochemical marker to monitor disease activity and response to therapy.

**Acromegaly Treatment**

**Desired Outcomes**

Patients with untreated acromegaly experience a two- to three-fold increase in mortality rate primarily because of cardiovascular and pulmonary diseases. Prolonged exposure to elevated GH and IGF-I can lead to serious complications in patients with acromegaly. Aggressively manage comorbid conditions such as hypertension, diabetes, dysrhythmias, coronary artery disease, and heart failure to prevent cardiovascular, pulmonary, metabolic, respiratory, and neuropathic complications. Normalization of GH and IGF-I concentrations lowers the mortality risk and may improve overall life expectancy. The goals of therapy are as follows:

- Reduce fasting morning GH and IGF-I concentrations as close to normal as possible
- Reduce tumor size to relieve tumor mass effect
- Prevent tumor recurrence
- Preserve normal pituitary function
- Improve clinical signs and symptoms
- Alleviate significant morbidities
- Reduce mortality rates to those of the general population

**Surgical Treatment**

According to the American Association of Clinical Endocrinologists (AACE) treatment guidelines for acromegaly, surgical resection of the pituitary tumor through transsphenoidal pituitary microsurgery is the treatment of choice for most patients with GH-producing pituitary adenomas. When performed by experienced surgeons, approximately 80% of patients with microadenomas and fewer than 50% of patients with macroadenomas achieve biochemical control. Complete
The patient will experience slow development of soft tissue overgrowth affecting many body systems. Signs and symptoms may progress gradually over 7 to 10 years.

**Symptoms**
- Headache and compromised visual function (loss of peripheral vision and blurred vision) caused by the actual tumor mass and its close proximity to the optic structures.
- Weakness, low blood sugar, or weight loss caused by disruption of adrenal function (ie, ACTH deficiency) by effect of tumor mass on the pituitary.
- Fatigue and weight gain caused by disruption of thyroid function (ie, TSH deficiency) by effect of tumor mass on the pituitary.
- Absence of regular menstrual periods (amenorrhea), impotence, and decreased libido caused by disruption of the gonadotropin secretion (ie, LH and FSH).
- Excessive sweating, joint pain, nerve pain, and abnormal neurologic sensations (paresthesias) related to elevated GH and IGF-I concentrations.

**Signs**
- Coarsening of facial features.
- Increased hand volume.
- Increased ring and shoe size.
- Increased spacing between teeth.
- Increased acne or oily skin.
- Enlarged tongue.
- Deepening of voice.
- Thick, irregular, and patchy skin discoloration.
- Enlarged nose, lips, and forehead (frontal bossing).
- Abnormal protrusion of the mandible (prognathia) and bite abnormalities.
- Inappropriate secretion of breast milk (galactorrhea).
- Abnormal enlargement of various organs (organomegaly) such as liver, spleen, and heart.
- Carpal tunnel syndrome caused by nerve compression from the swollen tissue.

**Laboratory Tests**
- Random GH concentration greater than 1 ng/mL (1 mcg/L; 45 pmol/L) or nadir GH concentration greater than 0.4 ng/mL (0.4 mcg/L; 18 pmol/L) after an OGTT and elevated IGF-I concentration compared with age-matched control values.
- Loss of other hormonal functions caused by tumor mass compression of the anterior pituitary.
- Measure prolactin concentration in all patients because prolactin cosecretion is common.
- Glucose intolerance may be present in up to 50% of patients.

**Additional Clinical Sequelae**
- Cardiovascular diseases: hypertension, coronary heart disease, cardiomyopathy, left ventricular hypertrophy, and arrhythmia.
- Osteoarthritis and joint damage develop in up to 75% of patients.
- Respiratory disorders and sleep apnea occur in up to 70% of patients.
- Type 2 diabetes mellitus develops in 56% of patients.
- Increased risk for the development of esophageal, colon, and stomach cancer.

**Other Diagnostic Tests**
- Perform magnetic resonance imaging (MRI) examination of the pituitary to locate the tumor and validate the diagnosis.
- Obtain serum prolactin concentrations to assess for hyperprolactinemia and hypopituitarism.
- Without obvious pituitary tumor but proven acromegaly, measurement of GHRH may be helpful to detect ectopic tumors.

Patient Encounter 1, Part 1: Acromegaly: Medical History and Clinical Presentation

A 61-year-old Caucasian woman has not seen her primary care provider for years prior due to financial issues and now complains of a sore on her abdomen, frequent headaches, and seeing “red and blue spots” in her vision. The patient has noticeably large facial features, manly arms, hands, and legs. She states, “I used to have those beautiful piano fingers until I reached my teens!” She had always believed her masculine features were due to growing up with five brothers.

PMH: Uncontrolled hypertension for 4 years; recently diagnosed type 2 diabetes mellitus
FH: Positive for diabetes in patient’s mother and five brothers
Allergies: NKDA
SH: Unemployed and uninsured, cleans 60+ hallways at her apartment to cover rent and utility; recently quit smoking
Meds: Lisinopril/hydrochlorothiazide 20/12.5 mg once daily; metformin 1000 mg twice daily; insulin glargine 20 units once daily; aspirin 81 mg once daily

Based on the information available, what signs and symptoms are suggestive of acromegaly?
What comorbidities are present in the patient as result of untreated acromegaly?
What diagnostic tests should be performed to confirm the patient’s diagnosis of acromegaly?

at least three times per day. The long-acting preparations of octreotide and lanreotide are considered the cornerstone of therapy because of improved patient adherence and acceptability. Somatostatin analogs modestly reduce pituitary tumor size in more than half of the patients with acromegaly. Their efficacy and safety have been demonstrated in long-term studies (up to 9 years with octreotide and 4 years with lanreotide). Overall, the somatostatin analogs normalize GH and IGF-I concentrations in 56% and 55% of patients, respectively. The efficacy of lanreotide autogel is comparable to that of depot formulations of lanreotide and octreotide in achieving clinical and biochemical control. Because somatostatin analogs can achieve substantial relief of clinical symptoms with significant reduction in tumor size, it is important to monitor patients for tumor recurrence if treatment is discontinued. It is not yet

[^3]: In the United States, initiate lanreotide at 90 mg every 28 days for 3 months and then titrate accordingly based on patient response. Different labeled dosing guidelines exist for the United Kingdom and Canada.

[^7]: Product labeling recommends a maximum of 30 mg IM every 4 weeks.

[^8]: Alternative dose administration protocol of twice a week or once a week has been used.

known whether use of somatostatin analogs before surgery has additional benefits over surgery alone.3

Somatostatin analogs are generally well tolerated. Transient gastrointestinal (GI) disturbances are common but usually subside within the first 3 months of therapy. Somatostatin analogs inhibit gallbladder contractility and decrease biliary sludge and asymptomatic gallstones (choledolithiasis). Cholelithiasis typically occurs in patients treated for 12 months or longer and is unrelated to age, gender, or dose. Somatostatin analog-induced gallstones are generally asymptomatic, and prophylactic therapy is usually not needed.6 Additionally, somatostatin analogs may alter the balance of counterregulatory hormones (ie, glucagon, insulin, and GH), resulting in either hypoglycemia or hyperglycemia. Octreotide also may suppress pituitary release of TSH, leading to decreased thyroid hormone secretion and subsequent hypothyroidism in 12% of treated patients. Close monitoring of thyroid function and glucose metabolism is recommended. Sinus bradycardia, conduction abnormalities, and arrhythmias have been reported with octreotide and lanreotide. Because of the potential adverse effects of the somatostatin analogs, concomitant use with insulin, oral hypoglycemic agents, β-blockers, or calcium channel blockers may require careful dosage adjustment. Somatostatin analogs may also alter the bioavailability and elimination of cyclosporine, and monitoring of cyclosporine serum concentration is necessary.

**GH-Receptor Antagonist** The advent of a GH-receptor antagonist represents a novel approach to the treatment of acromegaly. Pegvisomant is the only genetically engineered GH-receptor antagonist that blocks the action of GH. Pegvisomant is indicated for treatment of acromegaly in patients who have an inadequate response to surgery or radiation therapy. The effects of pegvisomant work independently of tumor characteristics, somatostatin, and dopamine receptors. Long-term safety and efficacy of pegvisomant (up to 5 years) from an ongoing postmarketing surveillance registry (ACROSTUDY) suggest a reasonable benefit/risk balance.13 In patients who were relatively unresponsive to other medical or surgical therapies, normal IGF-I concentrations were achieved in 63% of the patients treated with pegvisomant (mean dose of 18 mg/day)14 and in 69% to 100% of patients treated with pegvisomant and somatostatin analog therapy.15-17 Pegvisomant may have favorable effects on glucose tolerance (the body’s ability to metabolize glucose) and insulin sensitivity (capacity of cells to respond to insulin). However, use of pegvisomant is associated with significant dose-dependent increases in GH despite declining IGF-I concentrations. The dose-dependent increase in GH is troubling because it has been suggested that persistent elevation of GH concentration may be indicative of tumor growth. Although the incidence of pituitary tumor enlargement is low (3.2%), careful monitoring with periodic imaging scans is nonetheless warranted, especially when administering pegvisomant to patients at risk for visual damage from large tumors that may impinge on the optic chiasm.14 **Pegvisomant is recommended in patients who have inadequate response to somatostatin analogs, or as an adjuvant for patients who have only a partial response to somatostatin analogs.**3,7 The long-term use of pegvisomant appears to be well tolerated with a low incidence of adverse effects, including self-limiting injection-site reactions (2.2%) and elevated liver enzymes (2.5%).11 Although elevations of liver enzymes often are self-limiting and not associated with symptoms, hepatotoxicity has been reported in clinical trials, particularly in diabetic patients receiving combined pegvisomant and somatostatin analogs.17,18 Therefore, serum transaminases, total bilirubin, and alkaline phosphatase should be assessed before initiating therapy and periodically thereafter. Use caution when administering pegvisomant to patients with elevated liver function tests, and therapy should be discontinued in patients who present with clinical signs and symptoms of hepatic injury.

**Dopamine Agonists** Dopamine is one of the neurotransmitters that can increase GH secretion in healthy adults. However, dopamine agonists administered to patients with acromegaly exert the opposite effect and suppress GH release from the tumor. The first dopamine agonist used for acromegaly, bromocriptine, achieved normal IGF-I concentrations in fewer than 10% of patients.5 The large doses of bromocriptine required to achieve the desired response are often associated with dose-limiting toxicity such as GI discomfort and orthostatic hypotension. Cabergoline, a selective long-acting dopamine agonist with improved tolerability, can effectively reduce GH and IGF-I concentrations in approximately 40% of patients.3 Acromegalic patients with coexisting hyperprolactinemia achieve a more favorable response to cabergoline.3 Although orally administered dopamine agonists are the least expensive medical therapy for managing acromegaly, the major disadvantage is their relative lack of efficacy compared with existing therapeutic options. **KEY CONCEPT** Cabergoline may be considered for patients with modest elevation of GH and IGF-I concentrations less than two times the upper limit of normal. It may also be used as adjunctive therapy in patients unresponsive to monotherapy with somatostatin analogs or pegvisomant.7 Although cardiac valvular abnormalities have been observed in patients using higher doses of cabergoline for Parkinson disease, similar findings have not been reported in patients with acromegaly.3,10 Nonetheless, echocardiographic monitoring for potential cardiac abnormalities is warranted for patients who require prolonged, high-dose cabergoline therapy.

**Radiation Therapy** Radiation therapy is an important adjunctive therapy in patients with residual GH excess after surgery or pharmacologic therapy. Treatment involves the use of radiation to destroy rapidly growing tumor cells, and often results in a reduction in tumor size. A major complication of radiation therapy is hypopituitarism, requiring lifelong hormone replacement.7 There is also the potential for optic nerve damage if the pituitary tumor is near the optic tracts. Radiation therapy may take 10 to 20 years before its full effects become evident.5 Owing to this delay in onset of effectiveness, pharmacologic therapy with a somatostatin analog often is indicated as bridge therapy.3 Men and women who desire to have children should be warned that pituitary irradiation therapy may impair fertility because of subsequent gonadotropin deficiency.3

**Outcome Evaluation**

- Lifelong biochemical assessment is critical for determining therapeutic outcomes. Although some patients may experience a rapid decline in GH concentrations after surgery, stabilization of IGF-I concentrations usually occurs 3 months after surgery but rarely may be delayed for up to 12 months. Fully assess pituitary function 2 to 3 months after surgery.3 Monitor GH and IGF-I concentrations every 3 to 6 months postoperatively to assess treatment response.3 Obtain IGF-I concentrations annually in all postsurgical patients to monitor for potential pituitary tumor recurrence.3
- Assess MRI 3 to 4 months after surgery and 3 to 6 months after starting medical therapy.28 Because up to 10% of pituitary tumors may recur within 15 years after surgery, continual postoperative monitoring is recommended.
• For patients treated with somatostatin analogs, assess baseline fasting blood glucose, thyroid function tests, and heart rate. Thereafter, periodically monitor patients for adverse reactions such as GI disturbances, glucose intolerance, signs and symptoms of thyroid abnormalities, bradycardia, and arrhythmias in patients receiving long-term somatostatin analogs. Reevaluate IGF-I and GH concentrations at 3-month intervals to determine therapeutic response and inquire about symptoms of gallbladder disease (eg, intermittent pain in the upper right abdomen) during follow-up appointments. If normalization of GH and IGF-I concentrations are not fully achieved after 1 year, perform MRI 6 months later and annually thereafter to monitor tumor mass.

• For patients treated with a GH receptor antagonist, GH concentrations are not measured because pegvisomant is a modified GH molecule that is detected in commercial GH assays, resulting in falsely elevated GH concentrations. Therefore, monitor IGF-I concentrations to assess response to pegvisomant therapy. After appropriate dose titration, monitor IGF-I concentrations every 6 months. Concern for tumor growth requires careful monitoring of tumor size; therefore, perform MRI every 6 months during the first year of therapy and annually thereafter. Because of the potential for hepatotoxicity with pegvisomant therapy, it is mandatory to monitor liver enzymes prior to initiation of therapy, monthly during the first 6 months, quarterly for the next 6 months, and then biannually thereafter. More frequent monitoring of liver enzymes is warranted in patients with elevated liver enzymes at baseline.

• For patients receiving dopamine agonists, the maximal suppression of GH and IGF-I concentrations may take up to 3 months to achieve. After stable control of biochemical markers is achieved with dopamine agonists or somatostatin analogs, monitor GH and IGF-I concentrations annually.

• With conventional multidose radiation therapy, the most rapid decline in GH serum concentrations occurs within the first 2 years; monitor GH concentrations at the second year and annually thereafter. Patients who receive single-dose radiation therapy should be evaluated at 6-month intervals because response is observed earlier. Repeatedly assess pituitary function over the years after radiation therapy.

Growth Hormone Deficiency

Epidemiology and Etiology

In the United States, GH deficiency affects approximately 50,000 adults, with around 6000 new cases diagnosed annually. Approximately 10,000 to 15,000 children have growth failure owing to GH deficiency. Children may present with GH deficiency at any time during their developmental stages. The evaluation for GH deficiency in a child of short stature should be deferred until appropriate exclusion of other identifiable causes of growth failure, such as hypothyroidism, chronic illness, malnutrition, genetic syndromes, and skeletal disorders, has occurred. Several medications, such as somatostatin analogs, gonadotropin-releasing hormone (GnRH) agonists, methoxamine, phentolamine, isoproterenol, glucocorticoids, cimetidine, methylphenidate, and amphetamine derivatives, may induce GH insufficiency.

Pathophysiology

GH deficiency exists when GH is absent or produced in inadequate amounts. GH deficiency may be congenital, acquired, or result from disruption of the hypothalamus–pituitary axis. GH deficiency may be an isolated condition or occasionally be accompanied by another endocrine disorder (eg, panhypopituitarism). Because GH is frequently undetectable with random sampling, a stimulation or provocative test usually is performed to confirm the diagnosis. The gold standard for diagnosis of

Patient Encounter 1, Part 2: Acromegaly: Physical Examination and Diagnostic Tests

PE:
VS: BP 162/116 mm Hg, P 112 beats/min, RR 18 breaths/min, T 36.8°C (98.3°F), Ht 168 cm (5’6”), Wt 72 kg (159 lbs), BMI 25.8 kg/m²
ROS: (+) HA, (+) deepening of voice
HEENT: Visual field defects; head is elongated with bony prominence of the forehead, nose, and lower jaw; large fleshy nose
CV: RRR, normal S₁ and S₂; no murmurs, rubs, or gallops, (−) chest pain, palpitation, orthopnea, and leg swelling
Pulm: (−) SOB, (−) cough
GI: (−) Nausea, vomiting, and abdominal pain
Abd: Soft, nontender, nondistended; (−) bowel sounds, (−) hepatosplenomegaly
Skin: Skin lesion healing
Neuro: A & O x 3. Normal reflexes
Psychiatric: Normal mood and affect. Spacy, sweet, but needs extra help understanding instructions

Available Labs: Electrolytes and renal function are within normal limits. Fasting blood glucose concentration is 346 mg/dL (19.2 mmol/L); HgbA₁c is 11.9% (0.119; 107 mmol/mol), (+) microalbuminuria. GH concentration 1 hour after an OGTT is 83.6 ng/mL (83.6 mcg/L; 3779 pmol/L). Elevated IGF-I concentration at 998 ng/mL (998 mcg/L; 131 nmol/L). TSH is slightly low at 0.33 μU/mL (0.33 mU/L) and FT₄ is within normal range at 1.1 ng/dL (14.2 pmol/L)

MRI: (−) 12 mm benign pituitary adenoma extending toward the optic chiasm; no invasion into the cavernous sinus

If the patient is unwilling to undergo surgery, what pharmacologic treatment options are available for her?

Given that she is currently uninsured without a source of income, what factors need to be considered when choosing a pharmacologic treatment option?

Provide monitoring parameters to assess efficacy and safety to the patient starting on octreotide long-acting release.
Patient Care Process: Acromegaly

**Patient Assessment:**
- Assess the patient’s clinical signs and symptoms to determine the severity of acromegaly.
- Review the biochemical disease markers to assess the severity of acromegaly.
- Review the available diagnostic data to determine pituitary tumor size and location.
- Determine if the patient has a coexisting prolactin secreting tumor and if the tumor extends toward the optic chiasm or if it is continuous on the optic tracts.

**Therapy Evaluation:**
- Assess presence of acromegaly complications. Identify any significant comorbidities associated with acromegaly that require immediate treatment or early diagnosis.
- Determine treatment options the patient has tried in the past.
- Evaluate patient for presence of surgical contraindications to transsphenoidal microsurgery. Determine if the patient is able or willing to undergo surgical intervention.
- If surgical intervention does not achieve satisfactory disease control, select subsequent appropriate pharmacologic therapy based on patient-specific factors (see Figure 46–4). Be sure to consider if the patient has any contraindications or allergies to therapies (see Table 46–2).

**Care Plan Development:**
- Assess patient’s response and complications to surgical intervention. Measure both GH and IGF-I concentrations.

**Clinical Presentation and Diagnosis of Growth Hormone Deficiency in Children**

**General**
The patient will have a physical height that is greater than two standard deviations below the population mean for a given age and gender.

**Signs**
- The patient will present with reduced growth velocity and delayed skeletal maturation.
- Children with GH-deficient or GH-insufficient short stature also may present with abdominal obesity, prominence of the forehead, and immaturity of the face.

**Laboratory Tests**
- Patients will exhibit a peak GH concentration of less than 10 ng/mL (10 mcg/L; 452 pmol/L) after a GH stimulation test.
- Reduced IGF-I concentration also may be present.

**Follow-up Evaluation:**
- Assess biochemical markers annually once disease control is achieved.
- Routinely assess acromegaly complications; include blood pressure, glucose tolerance, fasting lipid profile, cardiac evaluations (if clinically indicated), colonoscopy, dual-energy x-ray absorptiometry (DEXA) scan (hypogonadal only), evaluation of residual pituitary function, and sleep apnea.

Clinical Presentation and Diagnosis of Growth Hormone Deficiency in Adults

General
The patient likely will have a history of childhood-onset GH deficiency, hypothalamic or pituitary disorder, or the presence of three or four other pituitary hormone deficiencies caused by head trauma, tumor, infiltrative diseases, surgery, or radiation therapy.

Symptoms
- Reduced strength and exercise capacity
- Defective sweating
- Psychological problems
- Low self-esteem
- Depression
- Fatigue or listlessness
- Sleep disturbance
- Anxiety
- Social isolation
- Emotional lability and impaired self-control
- Poor marital and socioeconomic performance

Signs
- Increased fat mass (especially abdominal obesity)
- Reduced lean body mass

- Reduced muscle strength
- Reduced exercise performance
- Thin, dry skin; cool peripheries; poor venous access
- Depressed affect, labile emotions
- Impaired cardiac function as evidenced by abnormal echocardiography or stress test results

Laboratory Tests
- Patients will exhibit a peak GH concentration of less than 5.1 ng/mL (5.1 mcg/L; 231 pmol/L) after a GH stimulation test. Insulin tolerance test (ITT) is the gold standard stimulation test. Low or low-normal IGF-I concentration also may be present. Presence of three or more pituitary hormone deficiencies with a low IGF-I concentration do not require further stimulation test.
- Increased low-density lipoprotein cholesterol, total cholesterol, triglycerides; decreased high-density lipoprotein cholesterol.
- Reduced bone mineral density associated with an increased risk of fracture.
- Increased insulin resistance and prevalence of impaired glucose tolerance.
- GH deficiency may be accompanied by the loss of other pituitary hormones.

Treatment

Desired Outcomes The goal of treatment for GH deficiency is to correct associated clinical symptoms. In children, prompt diagnosis and early initiation of treatment are important to maximize final adult height. In adults, the goal is to achieve normal physiologic GH concentrations in an attempt to reverse metabolic, functional, and psychological abnormalities.

Pharmacologic Therapy
Recombinant GH therapy is the main pharmacologic treatment for GH deficiency in both children and adults. It promotes skeletal, visceral, and general body growth; stimulates protein anabolism; and affects bone, fat, and mineral metabolism (see Table 46–1). GH therapy requires subcutaneous or intramuscular administrations. Because two-thirds of GH secretion normally occurs during sleep, it is recommended to administer GH injections in the evening. Many preparations of synthetic GH (somatropin) are available with a variety of injection devices to make administration more appealing and easier. Tev-Tropin is only approved for use in children, and other somatropin products such as Nutropin AQ, Humatrope, Norditropin, Genotropin, Omnitrope, and Saizen are approved in both children and adults.

Although comparative trials have not been conducted to date, recombinant GH products appear to have similar efficacy for treating GH deficiency as long as the regimen follows currently approved guidelines. GH secretion decreases with age; therefore, older adults with GH deficiency often require substantially lower replacement doses than younger individuals. The optimal therapeutic approach is to initiate GH therapy at lower doses and titrate according to clinical response, adverse effects, and IGF-I concentrations. Table 46–3 lists the recommended GH replacement doses for children and adults.

Conventional weight-based regimens are not recommended in adults due to lack of evidence supporting higher dosages in heavier individuals and greater potential for adverse effects. Maintenance doses may be lower with chronic GH therapy. For elderly patients, lower GH replacement doses often are adequate because of increased GH sensitivity.

Women with intact hypothalamic–pituitary–gonadal axis or on estrogen therapy (or oral contraceptives) generally require a higher GH dose than men due to decreased GH concentrations associated with estrogen. Carefully monitor patients requiring replacement therapy with estrogens, thyroid hormones, or glucocorticoids because of potential interactions with GH therapy. The potency of GH products is generally expressed as 3 international units (IU or mU) per 1 milligram of protein. Selection of an injection device depends on patient preference due to lack of differences in clinical outcomes among the various injection systems.
Evidence has suggested that GH treatment in GH-deficient children can increase short-term growth and improve final adult height.23 Beneficial effects of GH therapy in adults with GH deficiency have been demonstrated to normalize body composition and metabolic process; improve cardiac risk profile, bone mineral density, quality of life, and psychological well-being; and increase muscle strength and exercise capacity.24,33 The available data on cardiovascular and metabolic benefits of long-term GH replacement therapy in adults are inconsistent and additional research is needed to adequately assess the risks and benefits of long-term GH replacement.33 Overall, reduction in mortality with GH therapy remains to be established.

Practitioners should begin GH therapy as soon as possible to optimize long-term growth, especially for young children in whom GH deficiency is complicated by fasting hypoglycemia.22 Selection of the optimal GH replacement dose will need to be individualized depending on response, financial resources, and product availability. Although the appropriate time to discontinue therapy remains controversial in childhood GH deficiency, it is reasonable to continue GH replacement until the child has reached satisfactory adult height, achieved documented epiphyseal closure, or failed to respond to therapy.22 Management of the transition between pediatric and adult GH replacement remains a challenge because limited data are available. The secretion of GH during adolescence is normally lower than during puberty but higher than during adulthood. Therefore, for patients in a transition phase who may be restarting GH therapy, the initial dose for an adolescent is approximately the average of the pediatric dose required for growth and the adult dose.25 Starting GH therapy at a low dose and gradually titrating upward may decrease the potential for adverse effects. The optimal duration of treatment with GH therapy remains unclear, but lifelong therapy may be required. However, GH replacement should be discontinued if therapeutic benefit is not achieved after 2 years of therapy.25

In both children and adults, treatment with GH may mask underlying central hypothyroidism and adrenal insufficiency.25,35 Treatment with GH also may induce insulin resistance and lead to the development of glucose intolerance in patients with preexisting risk factors. Adults are more susceptible to dose-related adverse effects of GH-induced symptoms, such as edema, arthralgia, myalgia, and carpal tunnel syndrome, which may necessitate dose reductions in up to 40% of adults.

Children treated with GH replacement therapy rarely experience significant adverse effects. Benign increases in intracranial pressure related to GH therapy may manifest as headaches, visual changes, or altered concentrations of consciousness. This condition is generally reversible upon discontinuation of treatment. Often, GH therapy can be restarted with smaller doses without symptom recurrence. Presently, there is no compelling evidence that GH replacement therapy is associated with an increased risk of leukemia, solid tumor, or tumor recurrence.22,26,29 GH replacement therapy is contraindicated in all patients with active malignancy.29 However, in children with a history of malignancies, it would be prudent to wait for a 1-year tumor-free period (5 years for adults) before initiating GH therapy.22 Any patients treated for a prior malignancy may be at risk for a second malignancy and should be monitored carefully for tumor recurrence.25 Because deaths have been reported with use of GH in children with Prader-Willi syndrome who are severely obese or suffer from respiratory impairments, use of GH is contraindicated in these individuals. Evidence from the long-term surveillance study, Safety and Appropriateness of Growth Hormone treatment in Europe (SAGhE), remains inconclusive regarding GH therapy and its risk of increased morbidity. Therefore, further surveillance monitoring is warranted.36

### Outcome Evaluation

- Children with GH deficiency should be evaluated by a pediatric endocrinologist every 3 to 6 months. Monitor for an increase in height and change in height velocity to assess response to GH therapy.22,30 Every effort should be made

**Patient Care Process: GH Deficiency in Children**

**Patient Assessment:**
- Assess the child’s growth characteristics and compare the physical height with a population standard (e.g., Centers for Disease Control and Prevention Growth Charts).
- Obtain a thorough history and physical examination that may indicate the possible presence of GH deficiency.
- Exclude other identifiable causes of growth failure.
- Perform imaging tests of the hypothalamic–pituitary region to detect structural or developmental anomalies.
- Perform radiography of the wrist and hand to estimate bone age.
- Perform a provocative test to measure GH and IGF-I concentrations.

**Therapy Evaluation:**
- Determine if GH therapy is indicated. Make sure the child does not have any contraindications to GH therapy.
- Determine whether patient has prescription coverage.

**Care Plan Development:**
- Initiate GH replacement therapy based on patient preference (see Table 46–3).
- Assess response (increase in height and change in height velocity) and adverse effects of GH replacement therapy. Make dosage adjustments when appropriate.
- Provide patient education regarding disease state and drug therapy. Discuss with child and parents:
  - GH deficiency
  - Potential effectiveness and disadvantages of existing GH replacement therapy
  - Importance of adherence to therapy
  - Potential for adverse effects or need for lifelong replacement.

**Follow-up Evaluation:**
- Continue GH replacement therapy until child reaches satisfactory adult height, achieves documented epiphyseal closure, or fails to respond to treatment.
- Review and retest the child using adult GH deficiency diagnostic criteria when the child reaches final adult height.

---

**Patient Care Process: GH Deficiency in Adults**

**Patient Assessment:**
- Assess the patient’s clinical signs and symptoms to determine the severity of GH deficiency.
- Perform a provocative test to measure GH concentrations.
- Evaluate the patient for the presence of metabolic abnormalities and cardiovascular and fracture risks.

**Therapy Evaluation:**
- Determine if GH therapy is indicated. Make sure the patient does not have any contraindications to GH therapy.
- Determine whether patient has prescription coverage.

**Care Plan Development:**
- Initiate GH replacement therapy based on patient preference and characteristics (see Table 46–3)
- Assess the efficacy and adverse effects of GH therapy and consider if the patient’s therapy requires any dose adjustments based on IGF-I concentration, patient response, and adverse effects.
- Provide patient education regarding disease state and drug therapy:
  - Possible complications of GH deficiency
  - How to reduce the modifiable cardiovascular and metabolic risk factors
  - Potential disadvantages and effectiveness of existing GH replacement therapy
  - Importance of adherence to therapy
  - Potential for adverse effects or need for lifelong replacement

**Follow-up Evaluation:**
- Monitor for improvement of metabolic, cardiovascular, bone mineral density, and body composition parameters to assess response to GH therapy

---

to maximize height before the onset of puberty. After final adult height is reached and GH is discontinued for at least 1 month, retest and reevaluate the patient using the adult GH-deficiency diagnostic criteria.24,29,30

Although GH and IGF-I concentrations do not always correlate with growth response, measure IGF-I concentrations yearly to assess adherence to therapy and patient response. If the IGF-I concentrations are substantially above the normal range 2 years after GH replacement therapy, the dose should be reduced.29 IGF-I concentration may be used as a guide to gradually reduce replacement dose after epiphyseal closure.

Routine monitoring of fasting lipid profile, bone mineral density, and body composition in children is not typically required during GH replacement but should be done before and after discontinuation of therapy.22,30
In adults, measurement of serum IGF-I, along with careful clinical evaluation, appears to be the most reliable way to assess the appropriateness of the GH dose. Measure IGF-I serum concentrations 1 to 2 months during dose titration and semiannually thereafter.

Continuously monitor for dose-related adverse effects such as edema, arthralgia, myalgia, and carpal tunnel syndrome.

Evaluate psychological well-being.

Assess patients’ bone mineral density every 2 to 3 years.

When maintenance therapy is achieved, assess body composition (body mass index [BMI], waist circumference, waist-to-hip ratio), metabolic status (fasting glucose concentration, free thyroxine serum, hemoglobin A1c), cardiac risk factors (eg, fasting lipid profile), hypothalamic–pituitary–adrenal axis function (eg, morning serum cortisol response to ACTH stimulation), and testosterone concentrations at 6- to 12- month intervals.

PROLACTIN

Prolactin is an essential hormone for normal production of breast milk after childbirth. It also plays a pivotal role in a variety of reproductive functions. Prolactin is regulated primarily by the hypothalamus–pituitary axis and secreted solely by the lactotroph cells of the anterior pituitary gland. Under normal conditions, secretion of prolactin is predominantly under inhibitory control by dopamine. Increases of hypothalamic thyrotropin-releasing hormone in primary hypothyroidism can stimulate the release of prolactin.

Hyperprolactinemia

Hyperprolactinemia affects women of reproductive age more than men. Although this disorder occurs in less than 1% of the general population, the estimated prevalence in women with reproductive disorders is as high as 15% to 43%. The etiologies of hyperprolactinemia are presented in Table 46–4. Any medications that antagonize dopamine or stimulate prolactin release can induce hyperprolactinemia. Therefore, it is important to exclude medication-induced hyperprolactinemia from other common causes such as pregnancy, primary hypothyroidism, benign prolactin-secreting pituitary adenoma (prolactinoma), and renal insufficiency. Prolactinomas are the most common pituitary tumors. They are classified as microprolactinomas if they are less than 10 mm in diameter and as macroprolactinomas if they are 10 mm or larger in diameter.

In general, microprolactinomas rarely increase in size, but macroprolactinomas have the potential to enlarge and invade the surrounding tissues.

Pathophysiology

Hyperprolactinemia is a condition of elevated serum prolactin. It is the most common endocrine disorder of the hypothalamic–pituitary axis. High prolactin concentrations inhibit the release of gonadotropin–releasing hormone by the hypothalamus and subsequently suppress secretion of LH and FSH from the anterior pituitary (see Figure 46–1). High prolactin concentrations result in reduced gonadal hormone concentrations, often leading to reproductive dysfunction and galactorrhea (inappropriate breast milk production).

In combination with clinical symptoms, one or more serum prolactin concentrations greater than 25 ng/mL (25 mcg/L; 1087 pmol/L) will confirm the diagnosis of hyperprolactinemia in women. A number of physiologic factors such as eating, exercise, and stress can transiently elevate prolactin concentrations. Therefore, prolactin measurements should be obtained at rest, preferably in the morning under fasting conditions. If an intravenous line is present or planned, it is prudent to wait at least 2 hours after line insertion before measuring serum prolactin to decrease detecting transient physiologic increases in prolactin concentration. Although medication-induced hyperprolactinemia is typically associated with prolactin concentrations

*Atypicals (olanzapine and clozapine) other than risperidone may cause an early but transient elevation in prolactin.*

Clinical Presentation and Diagnosis of Hyperprolactinemia

General

Hyperprolactinemia most commonly affects women of reproductive age and is very rare in men.

Signs and Symptoms

Premenopausal women

- Headache and compromised or loss of vision caused by the prolactin-secreting tumor and its close proximity to the optic structures.
- Clinical presentation is associated with the degree of prolactin elevation:
  - Prolactin greater than 100 ng/mL (100 mcg/L; 4348 pmol/L): hypogonadism, galactorrhea, and amenorrhea
  - Prolactin 51 to 75 ng/mL (51–75 mcg/L; 2217–3261 pmol/L): oligomenorrhea (infrequent menstruation)
  - Prolactin 31 to 50 ng/mL (31–50 mcg/L; 1348–2174 pmol/L): decreased libido and infertility
- Increased body weight may be associated with a prolactin-secreting pituitary tumor.
- The degree of hypogonadism generally is proportionate to the degree of prolactin elevation.
- Excessive hair growth (hirsutism) and acne also may be present owing to relative androgen excess compared with low estrogen concentrations.

Men

- Decreased libido, decreased energy, erectile dysfunction, impotency, decreased sperm production, infertility, gynecomastia, and rarely, galactorrhea.
- Impotence is unresponsive to treatment and is associated with reduced muscle mass, loss of pubic hair, and osteoporosis.

Laboratory Tests

- Prolactin serum concentrations at rest will be greater than 20 ng/mL (20 mcg/L; 870 pmol/L) in men or 25 ng/mL (25 mcg/L; 1087 pmol/L) in women with at least three measurements.
- Obtain β-human chorionic gonadotropin (β-hCG) concentration to exclude pregnancy.
- Obtain TSH concentration to exclude primary hypothyroidism.
- Obtain blood urea nitrogen and serum creatinine tests to exclude renal failure.

Other Diagnostic Tests

- Perform MRI to locate the tumor, exclude a pseudoprolactinoma, and validate the diagnosis.
- Consider a bone mineral density test in patients with long-term hypogonadism.

Additional Clinical Sequelae

- The prolonged suppression of estrogen in premenopausal women with hyperprolactinemia leads to decreases in bone mineral density and significant risk for the development of osteoporosis.
- Risk for ischemic heart disease may be increased with untreated hyperprolactinemia.

of 25 to 100 ng/mL (25–100 mcg/L; 1087–4348 pmol/L), metoclopramide, risperidone, and phenothiazines have been associated with concentrations greater than 200 ng/mL (200 mcg/L; 8696 pmol/L). However, prolactin concentrations greater than 500 ng/mL (500 mcg/L; 21739 pmol/L) are almost always associated with the presence of a macroadenoma.29

Treatment

Desired Outcomes Because hyperprolactinemia is often associated with hypogonadism, the goals for management of hyperprolactinemia are as follows:39,40:

- Normalize prolactin concentration
- Restore normal gonadal function and fertility
- Prevent development of osteoporosis
- If a pituitary tumor is present:
  - Ablate or reduce tumor size to relieve tumor mass effect
  - Preserve normal pituitary function
  - Prevent progression of pituitary tumor or hypothalamic disease

General Approaches to Treatment Management of drug-induced hyperprolactinemia is to discontinue the offending agent, if clinically feasible, and replace it with an appropriate alternative that does not cause hyperprolactinemia.29 When the offending agent cannot be discontinued, cautious use of hormone replacement, biphosphonate therapy, or dopamine agonists may be considered depending on the patient’s clinical circumstances.25 Treatment options for the management of hyperprolactinemia include: (a) clinical observation, (b) pharmacologic therapy with dopamine agonists, (c) transphenoidal pituitary adenomectomy, and (d) radiation therapy. Clinical observation and close monitoring are justifiable in patients with asymptomatic elevation of prolactin.29
Pharmacologic Therapy Dopamine is the principal neurotransmitter responsible for the inhibition of prolactin secretion from the anterior pituitary. Thus, dopamine agonists are the main pharmacologic therapy used for management of hyperprolactinemia. Treatment with dopamine agonists has proven to be extremely effective in normalizing serum prolactin concentration, restoring gonadal function, decreasing tumor size, and improving visual fields. Patients with macroprolactinomas generally require a higher dose to normalize prolactin concentrations compared with patients with microprolactinomas.33

Two dopamine agonists—bromocriptine and cabergoline—are used for the management of hyperprolactinemia (Table 46–5).37,44 Because these two dopamine agonists are ergot derivatives, they are contraindicated in combination with potent cytochrome P-450 subfamily IIIA polypeptide 4 (CYP3A4) inhibitors, including protease inhibitors, azole antifungals, and some macrolide antibiotics. Furthermore, ergot derivatives can cause constriction of peripheral and cranial blood vessels. These medications are also contraindicated in patients with uncontrolled hypertension, severe ischemic heart disease, or peripheral vascular disorders.

Bromocriptine Bromocriptine directly binds to the D2 dopamine receptors. It normalizes prolactin concentration in 68% of patients and reduces tumor size in 62% of patients.32 Treatment with bromocriptine may also restore menses and fertility in women and improve testosterone secretion, sperm count and erectile function in men. It may also improve visual field defects associated with macroadenomas.33 Adverse effects such as nausea, dizziness, and orthostatic hypotension often limit 5% to 10% of patients from continuing treatment. To reduce risk of adverse effects and improve patient adherence, bromocriptine may be initiated at a low dose at bedtime.41 Slowly titrate up to the optimal therapeutic dose because most adverse effects subside with continual treatment. In women, if the adverse GI effects are not tolerable, bromocriptine can be administered vaginally at a reduced dose (2.5 mg/day).43 Owing to its short half-life of only 6 hours, bromocriptine must be administered in divided doses, which may compromise patient adherence.

Cabergoline Cabergoline has a higher affinity for D2 dopamine receptors than bromocriptine and possesses a long half-life, allowing for once- or twice-weekly administration. Cabergoline appears to be better tolerated than bromocriptine, and may be more effective in normalizing prolactin concentrations and restoring menses.46 It is also effective in treating hyperprolactinemia in patients who are resistant to or intolerant of bromocriptine and in men and women with microprolactinomas and macroprolactinomas.46 Given its favorable safety and efficacy profile and ease of administration, cabergoline has replaced bromocriptine as first-line therapy for the management of hyperprolactinemia.39 Withdrawal of pergolide from the US market due to increased risk for valvular heart disease raised concerns about the safety of cabergoline. However, to date, cabergoline use in patients with hyperprolactinemia or prolactinoma has not been associated with clinically significant valvular heart disease.

Nonpharmacologic Therapy In a small number of patients who have failed or are intolerant of dopamine agonists, transphenoidal adenomectomy may be necessary.39 Surgical treatment is also considered in patients with nonprolactin-secreting tumors or macroprolactinomas that jeopardize the optic chiasm.43 Nonetheless, surgical intervention does not reliably lead to long-term cure and may cause permanent complications.46 Radiation therapy is reserved for failures of both pharmacologic therapy and surgery.39 However, normalization of prolactin concentration with radiation therapy may take 20 years to show full benefit, and radiation-induced hypopituitarism may require lifelong hormone replacement.

| Table 46–5 | Comparison of Dopamine Agonists for Treatment of Hyperprolactemia37,44 |
|-----------------|-----------------|-----------------|-----------------|-----------------|
| **Bromocriptine (Parlodel)** | **Cabergoline** |
| Starting dose | 0.625–1.25 mg/day at bedtime | 0.5 mg/week or 0.25 mg twice/week |
| Titrating dose | 1.25 mg increments at 1-week interval | 0.5 mg increment at 4-week intervals |
| Usually effective dose | 2.5–15 mg/day | 1–2 mg/week |
| Maximal dose | 40 mg/day | 4.5 mg/week |
| Dosing frequency | Two to three divided doses per day | Once or twice weekly |
| Dosage in hepatic insufficiency | May be required in acute hepatitis or cirrhosis; no guidelines are available | Dose reductions may be recommended for patients with severe hepatic failure (Child-Pugh scores of 10 or higher) |
| Dosage in renal failure | None | None |
| Adverse effects | Dizziness, headache, syncope, nausea, vomiting, GI cramps, orthostatic hypotension, nasal congestion | Similar but orthostatic hypotension less common |
| Cost | Moderately expensive | More expensive |

Gl, gastrointestinal.
Patient Encounter 2: Hyperprolactinemia: Medical History, Physical Examination, and Diagnostic Tests

A 30-year-old woman presented to primary care clinic 6 months ago with complaints of infrequent menstruation and infertility. Since she started treatment for hyperprolactinemia 5 months ago, she was excited to see return of her regular menses for several months until she realized her last menstrual period was 4 weeks ago.

PMH: None
FM: Mother has hypertension, father with high cholesterol
SH: Married, dental assistant; sexually active (occasional use of condoms)
Meds: Prenatal vitamin one tablet daily; cabergoline 1 mg tablet weekly; acetaminophen 325 mg one to two tablets as needed for menstrual cramps
ROS: Negative, other than in history of present illness
PE:
HEENT: Ophthalmic examination reveals normal visual acuity and fields. (-) goiter
VS: BP 120/65 mm Hg, P 80 beats/min, RR 19 breaths/min, T 37.1°C (98.8°F)
CV: RRR, normal S1, S2; no murmurs, rubs, or gallops
Breasts: (-) Galactorrhea with no abnormalities
Abd: Soft, nontender, nontendosted; (+) bowel sounds; (-) hepatosplenomegaly
Rectal: Heme (-) stool
Labs: Electrolytes, renal and thyroid function, β-human chorionic gonadotropin (β-hCG) elevated at 6500 mIU/mL (6500 U/L)
Prolactin: Elevated prolactin at 89 ng/mL (89 mcg/L; 3870 pmol/L) today
Imaging: MRI revealed a 5 mm pituitary tumor (6 months ago)

What signs and symptoms were suggestive of hyperprolactinemia in the patient?
What nonpharmacologic and pharmacologic treatment options are available for her at this time?

Patient Care Process: Hyperprolactinemia

Patient Assessment:
- Assess the patient’s clinical signs and symptoms of hyperprolactinemia.
- Review the available diagnostic data to determine severity and exclude other common causes of hyperprolactinemia (see Table 46–4).
- Obtain a thorough medication history to exclude medication-induced hyperprolactinemia (see Table 46–4).

Therapy Evaluation:
- Determine the patient’s plan regarding pregnancy because this influences treatment selection.
- Determine if drug therapy is indicated. Make sure the patient does not have any contraindications or allergies to drug therapies.
- Determine whether patient has prescription coverage.

Care Plan Development:
- Provide patient education regarding disease state, and nondrug and drug therapy:
  - Risk factors associated with hyperprolactinemia
  - Potential disadvantages, safety and effectiveness of existing dopamine agonist therapy
  - Potential disadvantages, safety and effectiveness of surgery and radiation treatment
  - Importance of adherence to therapy
  - Potential for adverse effects or long-term complications

Follow-up Evaluation:
- Assess response and adverse effects of dopamine agonists. When appropriate, be sure to make dose adjustments (see Table 46–5).
- If the prolactin concentration remains normal for 2 years, reassess the need to continue treatment.

half-life, women who plan to become pregnant should discontinue the drug at least 1 month before planned conception. Microadenomas rarely cause complications during pregnancy. However, untreated macroprolactinomas carry about a 31% risk of tumor enlargement and potentially can jeopardize vision. Therefore, monitor female patients with macroprolactinomas closely for the development of headache and visual impairments. Baseline and routine visual field examinations are essential. Evidence of abnormal visual fields may indicate tumor growth and should be followed by an MRI. If tumors enlarge, bromocriptine is the preferred choice over cabergoline because of greater experience with this drug during pregnancy.
**Outcome Evaluation**

- Assess patients for tolerability to dopamine agonists.
- Monitor clinical symptoms associated with hyperprolactinemia every month for the first 3 months to assess therapeutic efficacy and assist with dose titration.
- Evaluate the patient for symptoms, such as headache, visual disturbances, menstrual cycles in women, and sexual function in men, to assess clinical response to therapy. If the prolactin concentration is normalized and clinical symptoms of hyperprolactinemia have resolved, monitor prolactin concentration every 6 to 12 months.
- If the prolactin concentration is well controlled with dopamine agonist therapy for 2 years with significant tumor reduction, gradually taper therapy to the lowest effective dose or consider discontinuing therapy. Check prolactin concentration after each dose reduction.
- If the prolactin concentrations remain unchanged for 3 months in a patient with macroprolactinoma or if an increase in symptoms or rise in prolactin concentration suggests the presence of tumor growth.
- Discontinuation of therapy in patients with macroprolactinomas usually leads to tumor regrowth and recurrence of hyperprolactinemia. This decision warrants careful consideration.

### Abbreviations Introduced in This Chapter

- **AACE**: American Association of Clinical Endocrinologists
- **ACTH**: Adrenocorticotropic hormone or corticotropin
- **ADH**: Antidiuretic hormone or vasopressin
- **β-hCG**: β-Human chorionic gonadotropin
- **BMI**: Body mass index
- **CT**: Computed tomography
- **CYP3A4**: Cytochrome P-450 subfamily IIIA polypeptide 4
- **DEXA**: Dual-energy x-ray absorptiometry
- **FSH**: Follicle-stimulating hormone
- **FT**: Free T
- **GABA**: γ-Aminobutyric acid
- **GH**: Growth hormone or somatotropin
- **GH**: Growth hormone–inhibiting hormone or somatostatin
- **GHRH**: Growth hormone–releasing hormone
- **GI**: Gastrointestinal
- **GnRH**: Gonadotropin-releasing hormone
- **HgbA**: Glycated hemoglobin A
- **IGF**: Insulin-like growth factor
- **IGF-I**: Insulin-like growth factor-I
- **IGF-II**: Insulin-like growth factor-II
- **IGFBP-3**: Insulin-like growth factor-bind protein-3
- **IM**: Intramuscular
- **ITT**: Insulin tolerance test
- **LAR**: Long-acting release
- **LH**: Luteinizing hormone
- **LHRH**: Luteinizing hormone–releasing hormone
- **MRI**: Magnetic resonance imaging
- **MSH**: Melanocyte-stimulating hormone
- **OGTT**: Oral glucose tolerance test
- **PRH**: Prolactin-releasing hormone
- **SAGHe**: Safety and Appropriateness of Growth hormone treatments in Europe
- **SC**: Subcutaneous
- **SR**: Slow release
- **SRL**: Somatostatin receptor ligand
- **T**: Triiodothyronine
- **T**: Thyroxine
- **TRH**: Thyrotropin-releasing hormone
- **TSH**: Thyroid-stimulating hormone or thyrotropin
- **ULN**: Upper limit of normal

### REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the principles of embryology and teratology.
2. Identify known teratogens and drugs of concern during lactation.
3. Compare the main sources of drug information relevant to pregnancy and lactation.
4. Evaluate the risks of a drug when taken during pregnancy or lactation.
5. Apply a systematic approach to counseling on the use of drugs during pregnancy and lactation.
6. Recommend the appropriate dose of folic acid to prevent congenital anomalies.
7. Describe physiologic changes during pregnancy and their impact on pharmacokinetics.
8. Choose an appropriate treatment for common conditions in a pregnant or lactating woman.

EPIDEMIOLOGY AND ETIOLOGY

Medication Use During Pregnancy

Most women take at least one medication during their pregnancy (average number of two to four, vitamins and minerals excluded). The most common types of medications used include vitamins and minerals, allergy medications, analgesics, antibiotics, antiemetics, laxatives, asthma medication, cold and flu remedies, levothyroxine, and progesterone. The safety profile of some medications taken during pregnancy is difficult to assess making it difficult to balance risks and benefits of treatment.

Background Risks of Anomalies in Pregnancy

Table 47–1 describes the baseline risks of congenital anomalies and some obstetrical complications observed in the general population—essential information to evaluate risks associated with medication use and to counsel pregnant women.

Causes of Congenital Anomalies

Although the risk of drug-induced teratogenicity is of concern, the actual risk of birth defects from most drug exposures is small. Medications are associated with less than 1% of all congenital anomalies, although they may play a more important role through interaction with genetic factors. Health professionals should know which medications have teratogenic risk. It is important to evaluate and manage drug use in pregnant women and women planning a pregnancy.

Other causes of anomalies include genetic causes in 25% of cases (inherited disease, gene mutation, chromosomal disorder), maternal infections (1%), maternal conditions (1%–3%; e.g., pregestational diabetes), multifactorial heredity (23%–50%), and unknown causes (34%–43%). Theoretical concerns regarding paternal exposure to genotoxic medication are reported, but currently no medication taken by a man has been proven teratogenic.

PATHOPHYSIOLOGY

Age of Pregnancy

The age of pregnancy can be defined as gestational or postconceptional age (PCA). Gestational age (GA) is the term used in clinical practice. It is calculated from the first day of the last menstruation or by ultrasound dating. PCA, calculated from the day of conception, is 14 days shorter than GA if the menstrual cycle is 28 days. Some references in the field of teratology and embryology refer to PCA to describe stages of pregnancy.

Principles of Embryology

Pregnancy can be divided into three development phases: implantation and predifferentiation, organogenesis (or embryogenesis), and fetogenesis. Table 47–2 describes these phases and possible drug effects if taken during these phases, and Figure 47–1 illustrates the critical periods of human in utero development. The risk of birth defects is usually higher during organogenesis.

Teratogens

A teratogen is an exogenous agent that can modify normal embryonic or fetal development. Teratogenicity can manifest as structural anomalies, functional deficit, cancer, growth retardation, neurologic impairment, or death (spontaneous abortion, stillbirth).

In utero exposure to medication at the end of the pregnancy can also lead to transient neonatal complications, such as withdrawal or side effects (e.g., opioids, selective serotonin reuptake inhibitors, antipsychotics, lithium).
Patient Encounter, Part 1

A 30-year-old woman comes to your office after a positive urine pregnancy test. You collect the following data:

**Estimated Gestational Age:** 5 weeks, regular menstrual cycles of 28 days
**PMH:** Bipolar disorder, hypothyroidism, one spontaneous abortion
**FH:** Diabetes, hypothyroidism, hypercholesterolemia
**SH:** Unemployed; cigarettes, one-half pack daily; no alcohol or illicit substances
**Meds:** Lithium 900 mg orally at bedtime; quetiapine 50 mg orally at bedtime; levothyroxine 50 mcg orally in the morning; all discontinued 1 week ago
**Allergy:** Dust mites
**ROS:** Morning nausea; tiredness
**VS:** Wt 198 lb (90 kg)/Ht 63 in (160 cm), BP 110/72 mm Hg, P 70 beats/min, RR 12 breaths/min; slight enlargement of thyroid

**How will you confirm gestational age?**
**What prenatal work up would you perform at this time?**
**What is the appropriate counseling at this time?**
**What are the risks of drugs taken in the first weeks of pregnancy? What resources will you use to find the appropriate information?**
**What do you recommend for her pharmacologic treatment?**

Although we use the term teratogen in this chapter, we agree with some authors who prefer to use instead teratogenic exposure. Teratogenic exposure considers level (dose) and timing of exposure during pregnancy to determine whether it could lead to a higher risk of a specific malformation.¹

Criteria have been proposed to determine whether a causal relationship between congenital anomalies and a medication is plausible (teratogenic effect).² Exposure to the medication must have happened during the critical period of development of the organ for which a malformation is noticed (see Figure 47–1). Also, a pattern of anomaly or a specific syndrome must be present, and the observed effects must be reproducible in at least two studies conducted in different populations. A rare anomaly associated with a rare exposure is also indicative of a teratogenic effect (eg, ear anomalies and isotretinoin).

Other criteria, listed below, are considered (the probability of finding an association increases with the number of criteria):
- **Strength of the association**
- **Same effects observed in animal studies**
- **Biological plausibility based on pharmacologic effect**
- **Higher incidence of the anomaly in the population with the period of use of the medication (eg, thalidomide and limb anomalies)**
- **Dose–response relationship**

With these criteria, there are approximately 30 medications or classes of medications that are considered teratogens (Table 47–3). Drugs not on this list are not necessarily safe to use during pregnancy. We must be careful not to interpret a lack of data as an absence of risk. If a medication is on this list, it does not mean that it is contraindicated during pregnancy. Severity and occurrence of malformations vary from one agent to another; some are always contraindicated, but some others can be used when benefits outweigh potential risks.

Some medications associated with a higher risk of malformation are not included in Table 47–3 since they do not meet all the teratogenicity criteria. For example, benzodiazepines (oral cleft), lamotrigine and topiramate (oral clefts), paroxetine (cardiac septal anomalies), pseudoephedrine (gastrochisis).

**RISK EVALUATION**

**Desired Outcomes**

The goal of drug use during pregnancy and lactation is to treat maternal or fetal conditions effectively when necessary while minimizing risk to the developing embryo/fetus or the neonate.

**Medication and Pregnancy**

**Data Published on Medication Safety During Pregnancy**

Classical randomized controlled trials are usually not available to evaluate the safety of medications used during pregnancy and lactation. Most available data on drug safety during pregnancy come from postmarketing reports.

Animal studies, now mandatory before marketing a medication, can identify high-risk medications and prevent congenital anomalies. However, they must be interpreted with great caution because of many limitations; the major ones are that different species do not share the same pharmacodynamics and pharmacokinetics for the same medication, and usually much higher doses than those used in clinical settings are tested.¹¹

Case reports and case series provide the first published data on the use of medications during pregnancy. A causal relationship between a single case report and an anomaly cannot usually be established unless a rare anomaly is repeatedly associated with the use of a specific medication.

Cohort studies and company registries seek to compare the risks observed after exposure to a medication with the risk observed in a control group or in the general population. When

*(Continued)*
studying structural anomalies, it is important to select women exposed to medication during organogenesis. Cohort studies usually are not powerful enough to assess the risk associated with rare anomalies. When a signal of association between an anomaly and a drug exposure is observed, a case-control study, which has more power to detect rare anomalies, can be conducted to clarify the relationship. When several studies have been published using very similar methodologies, meta-analyses can be conducted to yield higher statistical power.

Sources of Information on the Use of Drugs During Pregnancy and Lactation

Some specialized information sources provide data on the use of medications during pregnancy and lactation (Table 47–4).

The 1979 Food and Drug Administration (FDA) regulations establishing pregnancy categories for drugs (A, B, C, D, and X) are well known to health care providers. This categorization has long been criticized by experts who recommend instead relying on other information sources. They assert that the categories are too simplistic, can lead to a risk misperception, and do not take into account important information such as expected incidence, severity of anomalies, degree of risk, gestational timing of exposure, and route of administration. In May 2008, the FDA proposed that the categories be removed and replaced by a short statement including description and risk of fetal defects, sources of data (animal or human), comparison with population baseline risk of birth defects, and the relationship with the dosage. An equivalent section for drug use during lactation will be inserted. This new regulation is in the process of being implemented.

Meanwhile, clinicians should rely on other information sources to evaluate the risk of a medication during pregnancy.

Communication of Information

Communication of data on medication use during pregnancy can be challenging:

- Data may be limited or contradictory.
- Taking medications during pregnancy is a source of anxiety.
- Pregnant women tend to overestimate their risk associated with undertreating their condition.
- Most people do not properly understand numbers and probability.

The objective is to give precise data that will help the patient make an informed decision for her health and the health of her

*Stages of pregnancy in this table are calculated after last menstrual period (gestational age) and not after conception to be more clinically useful. CNS, central nervous system; LMP, last menstrual period; NTD, neural tube defect.

Data from Refs. 6, 7, 9, and 10.
baby. Unconfirmed hypotheses should not be communicated. Information should include a well-grounded assessment of risks, including baseline risks in the general population, risks associated with the medication, and risks of not treating the disease during pregnancy. When discussing numbers (eg, percentages, probabilities), some tips to facilitate effective risk communication are:

- Use absolute risks instead of relative risks.
- Use negatively and positively framed information at the same time (eg, 3% chance of having a malformed child; 97% chance of having a normal child).
- Use the same denominator when discussing probabilities.

Finally, to determine a woman’s risk of birth defects, obtain good medical, obstetrical, and pharmacotherapeutic histories (including over-the-counter medications and natural health products) and take into account exposures to alcohol, tobacco, and other recreational drugs.

### Preconception Care

Adverse pregnancy outcomes, including prematurity, low birth weight, and birth defects, are major health concerns. One contributing factor to adverse outcomes is the late start in prenatal care, which can delay the identification and modification of risk factors that can affect pregnancy outcomes. Strategies to improve pregnancy outcomes include identifying and treating nutritional deficiencies and disorders, taking folic acid, avoiding alcohol and substance abuse, smoking cessation, optimizing the management of chronic illnesses and genetic disorders (eg, diabetes, epilepsy, hypertension, maternal phenylketonuria), screening for infections (eg, human immunodeficiency virus, sexually transmitted infections), appropriate vaccination, pregnancy planning, and reaching a healthy weight.

### Folic Acid

Approximately 1 in every 1000 pregnancies is affected by a neural tube defect (NTD). Data indicate that multivitamins containing folic acid reduce NTD and other congenital anomalies including oral clefts and cardiovascular, limb, and urinary malformations. All women of childbearing age should be counseled on the appropriate dose of folic acid to prevent congenital anomalies. The American College of Obstetricians and Gynecologists (ACOG) and the US Preventive Services Task Force recommend that all women of childbearing age take 0.4 to 0.8 mg of folic acid daily, beginning 1 month before pregnancy and through the first 2 to 3 months. Women at higher risk of NTD (eg, previous child or first-, second-, or third-degree relative with a NTD, those with prepregnancy diabetes, those with epilepsy taking carbamazepine or valproic acid) should take 4 mg of folic acid per day.

### Iron Supplements

Anemia during pregnancy is defined as a hemoglobin level less than 11 g/dL (110 g/L; 6.83 mmol/L) during the first and third trimesters and less than 10.5 g/dL (105 g/L; 6.52 mmol/L) during the second trimester. Maternal symptoms of anemia include fatigue, palpitations, and decreased resistance to exercise and infections. Fetal risks are prematurity, low birth weight, and perinatal death. All pregnant women should be screened for anemia, and those with iron deficiency should be treated with oral iron preparations in addition to prenatal vitamins. Iron supplementation decreases the prevalence of maternal anemia at delivery. It is unclear whether supplementing nonanemic pregnant women will improve perinatal outcomes.

### Impact of Physiologic Changes During Pregnancy on Pharmacokinetics

- **Absorption** Drug absorption is affected in several ways during pregnancy. Decreased gastrointestinal transit can delay drug peak effect, prolonging the time of contact of drugs with the intestinal mucosa, and possibly enhancing absorption of certain drugs. Higher gastric pH may affect absorption of weak bases or acids. Skin, tissue, and lung absorption might also be increased by physiologic changes during pregnancy.

- **Distribution** Volume of distribution increases for most drugs during pregnancy due to plasma volume expansion and the presence of amniotic fluid, the placenta, and the fetus. This results in a decrease in maximal concentrations of drugs. In addition, hypoalbuminemia and decreased protein binding increases free fraction of some medications.

- **Metabolism** During pregnancy, the activity of some isoenzymes is increased (eg, CYP3A4, CYP2A6, CYP2D6, CYP2C9), while activity of others is decreased (eg, CYP1A2, CYP2C19). Net impact on drug effect is unpredictable since there is a wide interindividual variability, and some drugs are metabolized by several isoenzymes.

- **Renal Elimination** Renal blood flow and glomerular filtration increase significantly during pregnancy. The impact of this is more important for drugs that are eliminated in the urine which results in a decrease in their half-lives.

### Medication and Lactation

According to the 2012 policy statement from the American Academy of Pediatrics (AAP), mothers should breast-feed exclusively for 6 months and continue for 1 year if possible. Approximately 75% of mothers initiate breast-feeding at birth. However, exclusive breastfeeding drops to 17% at 6 months, as many new mothers supplement breast-feeding with other foods or quit entirely by this point.

### Drug Transfer into Breast Milk

To study drug effects, breast-fed infant’s serum drug levels could be measured to evaluate safety; however, these data are often unavailable. In most instances, the approximate quantity of drug ingested by the breast-fed infant is estimated using published measured drug concentrations in breast milk. With these data, the percentage of pediatric dose or the relative infant dose (percentage of weight-adjusted maternal dose) can be calculated, assuming an average of 150 mL/kg/day of milk ingested by a breast-fed infant.

- **Percentage of pediatric dosage =**
  \[
  \frac{\text{Quantity of medication taken from milk by the baby (mg/kg/day)}}{\text{Usual initial daily pediatric dose (mg/kg/day)}} \times 100
  \]

- **Weight adjusted maternal dose or relative infant dose =**
  \[
  \frac{\text{Quantity of medication taken from milk by the baby (mg/kg/day)}}{\text{Maternal dose adjusted by weight (mg/kg/day)}} \times 100
  \]

In the latter equation, maternal dose refers to the dose used by patients in the published study or case report, not to the dose of your actual patient.

</tr>
</tbody>
</table>

↑, increase; ↓, decrease; ↔, unchanged; Cmax, maximum serum concentration; Cl, clearance; ff, free fraction; T, trimester; t½, elimination half-life; LMWH, low-molecular-weight heparin; Ctotal, total concentration; SSRI, selective serotonin reuptake inhibitor.

Data from Refs. 6 and 18.

---

Usually, a percentage of less than 10% of the pediatric dose or, when a pediatric dose is not available, a percentage of less than 10% of weight adjusted maternal dose, is acceptable in full-term healthy infants unless a drug has a toxic side effect profile.20

### Drug Pharmacokinetics

If clinical data are unavailable on drug transfer into breast milk, choose drugs that are highly protein bound, have a high molecular weight, have a short half-life, have no active metabolites, and are well tolerated by children.20

### Drugs of Concern During Breast-Feeding

**KEY CONCEPT** Most drugs are safe during breast-feeding. However, some drugs are of concern and require a more thorough assessment by the clinician (Table 47–6). One should also consider additive side effects of medication for the baby when the mother is taking several medications.

### CONDITIONS PREVALENT IN PREGNANCY AND LACTATION

**KEY CONCEPT** When possible, treat conditions occurring during pregnancy with nonpharmacologic treatments instead of drug therapy. Evaluate the need for treatment, including benefits and risks. Avoid treatments that do not show evidence of benefit or that can be delayed until after pregnancy or breast-feeding.

---

For chronic diseases, please refer to the relevant chapter where you will find considerations during pregnancy under “Special populations”.

### Nausea and Vomiting of Pregnancy (NVP)

As many as 85% of pregnant women suffer from nausea or vomiting.21 Nonpharmacologic measures, such as lifestyle (rest, avoidance of nausea triggers) and dietary changes (small and frequent meals, fluid restriction during meals, avoiding spicy or fatty foods, consuming crackers upon rising) should be used as first-line management. Acupuncture and acupressure also can be helpful.21

The combination of pyridoxine and doxylamine is the first-line pharmacologic treatment of NVP. When this combination is insufficient, other drugs such as metoclopramide, diphenhydramine, or ondansetron can be prescribed (Table 47–7).24

### Pain

Pregnant or lactating women experience pain from preexisting conditions or from temporary pathologies (eg, vaso-occlusive crisis in sickle cell disease, fibromas, migraine, etc)

The general principles of treatment are6,7,25:

- Maximize nonpharmacological measures
- Acetaminophen is the safest analgesic during pregnancy
- If medications are required, avoid nonsteroidal anti-inflammatory drugs (NSAIDs) during the third trimester, and use them with caution otherwise
Tocolytic Agents

Antenatal Corticosteroids

Chronic use may lead to dental staining or -

For migraine, triptan use remains controversial. Sumatriptan

Hormonal contraceptives with ethinylestradiol

There is a lack of information for some medications

Opiates are not associated with a higher risk of

• Opiates are not associated with a higher risk of malformations. However, close neonatal monitoring is necessary due to possible withdrawal if opiates are taken regularly near delivery. Limited data exist for some opiates during the first trimester, eg, for fentanyl and tramadol

• There is a lack of information for some medications (eg, pregabalin)

• For migraine, triptan use remains controversial. Sumatriptan has not been associated with a higher risk of birth defects. It can be used but not routinely.

Urinary Tract Infections

Urinary tract infections during pregnancy, including asymptomatic disease, increase the risk of hypertension, low birth weight, and perterm delivery.3

Asymptomatic bacteriuria and cystitis cause acute pyelonephritis more often in pregnancy than in nonpregnant women.26 Acute pyelonephritis may lead to septic shock and adult respiratory distress syndrome and should be treated aggressively with intravenous antibiotics. Outpatient treatment with intramuscular therapy alone or followed by oral treatment is feasible for some women (eg, stable and pregnancy less than 24 weeks).26 Treatment reduces pregnancy complications.26–28

Antimicrobial therapy should target Escherichia coli infection and should vary according to local bacterial resistance (see Table 47–7).26 Avoid trimethoprim-sulfamethoxazole during organogenesis (congenital malformations) and near term (theoretical risk of neonatal jaundice).2 Quinolones should be reserved for resistant infections due to theoretical concerns of arthropathy.2

Repeat urine culture 10 to 14 days after completion of acute pyelonephritis therapy and monthly thereafter. After completion of the acute episode of pyelonephritis, recommend suppressive therapy prophylaxis for the remainder of the pregnancy and for 4 to 6 weeks after delivery (See Table 47-7).26

Preterm Labor

Preterm birth, especially before 32 weeks of pregnancy, is the major cause of short- and long-term neonatal mortality and morbidity. The underlying pathophysiologic conditions are diverse, and most are unknown. There is wide variation in management, diagnosis, and treatment of preterm labor across the world.

Antenatal Corticosteroids

The most beneficial intervention in preterm labor is administration of antepartum corticosteroids. Provide a single course of antenatal corticosteroids to women at risk of preterm delivery within 7 days between 24 and 34 weeks’ gestation (see Table 47–7).29 This approach decreases the incidence and severity of neonatal respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, and death.29 Current data do not support the use of repeated courses of corticosteroids (see Table 47–7).30

Tocolytic Agents

Tocolytic therapy is used when preterm labor occurs before 33.6 weeks to delay delivery in order to complete a course of corticosteroids and allow transfer of the mother to a center with neonatal intensive care facilities. Tocolytics include magnesium sulfate, β-mimetics (terbutaline), prostaglandin inhibitors (indomethacin), oxytocin receptors blockers (atosiban), and calcium channel blockers (nifedipine) (see Table 47–7).30 All these agents are effective in delaying delivery by 48 hours. Data indicate that

CHAPTER 47  |  PREGNANCY AND LACTATION: THERAPEUTIC CONSIDERATIONS

Clinical Confirmation and Associated Problems of Pregnancy and Lactation

**Confirmation of Pregnancy**
Positive urine or blood human chorionic gonadotropin followed by positive ultrasound, fetal heart sounds, and/or fetal movement.

**Pregnancy Dating and Gestational Age**
Calculated from the first day of the last menstrual period. An ultrasound between 10+0 and 13+6 weeks determines gestational age based on crown-rump length and identifies multiple pregnancies. Due dates typically are estimated at 40 weeks of gestation; however, infants delivered between 37 and 42 weeks are considered full term.

**Pregnancy Symptoms**
- First trimester: Menstrual spotting, missed menses, fatigue, breast tenderness, increased urination, mood swings, nausea/vomiting, headache, heartburn, constipation
- Second trimester: Frequent urination, heartburn, constipation, dry skin, edema, linea nigra, melasma
- Third trimester: Backache, edema, shortness of breath, insomnia

**Routine Pregnancy Visits**
In a normal, uncomplicated pregnancy, visits should occur monthly until 28 weeks of gestation, every 2 to 3 weeks from 28 to 36 weeks of gestation, and then weekly until delivery. Assess for each of the following at each visit:
- Blood pressure
- Weight
- Urine protein (dipstick)
- Uterine size
- Fetal heart rate
- Fetal movement

**Routine Lab Testing for Normal Pregnancies (First Trimester Unless Otherwise Indicated)**
- Hemoglobin and hematocrit for anemia (repeated at 26–32 weeks)
- Blood type, Rh, red blood cell antibody screening
- Human immunodeficiency virus
- Venereal Disease Research Laboratory (VDRL) slide test for syphilis
- Rubella immunity
- Varicella immunity
- Hepatitis B surface antigen
- Urinalysis with culture for bacteriuria
- Gonorrhea and chlamydia
- Cervical cytology
- Screens for Down syndrome and neural tube defects (between 11 and 20 weeks)
- Gestational diabetes screening (at 24–28 weeks)
- Group B Streptococcus screening (at 35–37 weeks)
- Women at high risk for these conditions should be tested at the first visit:
  - Hypothyroidism
  - Type 2 diabetes
  - Sickle cell disease or thalassemia
  - Hepatitis C
  - Tuberculosis
  - Bacterial vaginosis

**Selected Problems Experienced During Pregnancy or Lactation**
- Hyperemesis gravidarum. Severe, persistent nausea and vomiting during pregnancy accompanied by dehydration, electrolyte disturbance, ketonuria, and weight loss.
- Urinary tract infection. Bacteriuria often asymptomatic in pregnancy. Diagnosed by positive urine culture.
- Bacterial vaginosis. Clinically diagnosed by presence of three of the following (Amsel criteria):
  - White, homogenous, noninflammatory discharge
  - Clue cells on microscopic examination
  - Vaginal pH greater than 4.5
  - A fishy odor before or after addition of 10% potassium hydroxide (ie, “whiff” test)
- Vulvovaginal candidiasis. Typical symptoms include vaginal itching and whitish discharge.
- Sexually transmitted infections: Refer to Table 47–8.
- Preterm labor. Onset of uterine contractions and cervical modification which may lead to delivery prior to 37 weeks of gestation.
- Preterm premature rupture of the membranes. Rupture of the amniotic membranes before 37 weeks and before active labor.
- Abruptio placenta. Sudden detachment of the placenta presenting with uterine bleeding, abdominal pain with or without maternal and fetal hemodynamic compromise.
- Group B streptococcus colonization. Diagnosed by positive culture on vaginal and rectal swab.
- Gestational diabetes. See Chapter 43.
- Gestational hypertension. Asymptomatic or presence of neurologic, hepatic, or cardiovascular symptoms. Check for proteinuria.
- Mastitis. Characterized by localized redness, tenderness, and warmth on one breast accompanied by fever and flu-like symptoms. Although uncommon, symptoms also may be bilateral.
- Breast candidiasis. Typical symptoms include nipple pain, itching, burning, and/or breast pain that persist after feeding.

MRSA, methicillin-resistant *Staphylococcus aureus*; NTD, neural tube defect; po, orally; RDA, recommended daily allowance.

Data from Refs. 6, 10, 15, 17, 21, 25–31, and 33–49.
indomethacin and nifedipine have the highest probability of delaying delivery and improving neonatal and maternal outcomes. Combined tocolytics or prolonged or repeated tocolytic therapy may increase fetal risk without evidence of efficacy.

The FDA has advised against the use of terbutaline for tocolysis due to the risk of serious side effects including increased heart rate, transient hyperglycemia, hypokalemia, cardiac arrhythmias, pulmonary edema, and myocardial ischemia.

**Neuroprotection**

Magnesium sulfate given to women at imminent risk of preterm delivery up to 33.6 weeks gestation decreases the incidence of death, cerebral palsy, and gross motor dysfunction. (see Table 47–7).

**Antibiotics**

In the presence of preterm premature rupture of membranes (PPROM), 2 days of parenteral ampicillin/erythromycin followed by 5 days of oral amoxicillin and erythromycin are associated with a delay of delivery and reduction in maternal and neonatal morbidity (see Table 47–7).

**Progestrone**

Progestrone is used to prevent preterm birth in women with previous preterm delivery and may also be used in women with a sonographic short cervix. (see Table 47–7).

**Group B Streptococcus Infection**

Ten percent to 30% of pregnant women are colonized by group B streptococcus (GBS) at term. Maternal transmission of GBS during delivery can cause neonatal sepsis and death. Antibiotic therapy is effective in reducing the incidence of early-onset neonatal GBS infection when administered to high-risk groups including women with GBS vaginal/rectal colonization, GBS bacteriuria in the current pregnancy, and those who previously delivered a neonate with GBS disease.

All women should be screened for GBS colonization using a vaginal-rectal swab between 35 and 37 weeks of gestation unless they had a proven GBS bacteriuria during the current pregnancy or a previous neonate with GBS disease. If treatment is indicated, it should be started at the time of membrane rupture or onset of labor, whichever comes first and continued until delivery (see Table 47–7).

**Postpartum Hemorrhage**

Postpartum hemorrhage is generally defined as blood loss greater than 500 mL after vaginal delivery or 1000 mL following a caesarean section. Uterine atony accounts for up to 80% of primary postpartum hemorrhage, but vaginal or cervical trauma, retained placenta, and coagulopathies are also implicated. Supportive measures should be implemented, and the most likely cause of bleeding should be identified and corrected.

Oxytocin and carbetocin (long-acting analog of oxytocin) can prevent excessive blood loss associated with delivery and caesarean section. If this fails, use uterotonic, eg, methylergonovine, carboprost tromethamine, dinoprostone, and misoprostol, which are effective in the treatment of postpartum hemorrhage secondary to uterine atony, used separately or in combination. Methylergonovine should not be administered to hypertensive women. Carboprost tromethamine should be used with caution in asthmatic women. As a last resort, tranexamic acid, an antifibrinolytic agent can be used. Surgical management ranging from uterine tamponade to hysterectomy is used in unresponsive postpartum hemorrhages.

**Thyroid Disorders**

Notice that the thyroxine-stimulating hormone (TSH) reference range is lower in pregnancy, 0.1 to 2.5 μIU/mL (0.1–2.5 mIU/L) in the first trimester and 0.3 to 3.0 μIU/mL (0.3–3.0 mIU/L) thereafter. Transient gestational hypothyroidism or hyperthyroidism can occur and have adverse effects on the pregnancy and the fetus/neonate, even if subclinical.

Universal screening of thyroid disorders (TSH or thyroid peroxidase antibody) in pregnancy is debated. Subclinical hypothyroidism should be treated, although there are no solid data on the impact of thyroid replacement therapy on maternal and neonatal morbidity, especially in women without thyroid peroxidase antibodies.

Gestational hyperthyroidism associated with hyperemesis gravidarum is self-remitting and does not require antithyroid treatment. In maternal hyperthyroidism, propylthiouracil is used in the first trimester (methimazole is associated with fetal malformations) and methimazole is used thereafter (propylthiouracil is associated with an increased risk of hepatotoxicity) (see Table 47–7). Close fetal and neonatal monitoring is necessary to detect signs of hypothyroidism (induced by antithyroid drugs)
or hyperthyroidism (induced by maternal thyroid-stimulating antibodies).

TSH level should be evaluated 6 to 12 weeks after delivery in all women with thyroid disorders during pregnancy. Thyroid replacement drugs and antithyroid drugs can be used during lactation.20

Hypertension
Both preexisting (chronic) and gestational hypertension increase the risk of maternal and perinatal morbidity and mortality. Women with preeclampsia, a syndrome generated by endothelial dysfunction, may present with seizures (eclampsia), neurologic, hepatic, and renal or coagulation complications, as well as fetal death and intrauterine growth restriction. Delivery is the only treatment for preeclampsia. Intravenous magnesium sulfate is used to prevent eclampsia (see Table 47–7).33–44 During pregnancy, severe hypertension (systolic blood pressure greater than or equal to 160 mm Hg or a diastolic blood pressure greater than or equal to 110 mm Hg) is an emergency and should be treated aggressively, but a limited number of drugs can be used (see Table 47–7). Methyldopa, labetalol, and nifedipine are accepted as first-line treatments for nonsevere hypertension, however, the blood pressure level at which they should be used is debated. Caution is advised with atenolol (intrauterine growth restriction). Angiotensin-converting enzyme inhibitors, angiotensin II receptor antagonists, or renin inhibitors (fetopathy) are contraindicated.44

In high-risk women, to prevent preeclampsia, initiate early in pregnancy, low-dose aspirin (75–160 mg daily). Also, if low dietary intake, start calcium supplements (1–2 g/day).44

See all women with hypertensive disorders 6 to 12 weeks after delivery to measure blood pressure and proteinuria, assess cardiovascular risk markers, and counsel them on healthy diet, lifestyle modification, future pregnancy, and risk of cardiovascular diseases.

Anticoagulation
The risk of thromboembolic events is increased during pregnancy and even more during the postpartum. Anticoagulation is required in some women, even if they were not anticoagulated before pregnancy.7,10

Low-molecular-weight heparins are preferred over unfractionated heparin due to a favorable pharmacokinetic profile. Both are safe during pregnancy and lactation. Doses should be specific to the underlying condition.

Warfarin is associated with fetal malformations when used between 6 and 12 weeks of pregnancy and with fetal and maternal bleeding when used during the third trimester and delivery (see Table 47–3).210 However, it could be used by some women with prosthetic heart valves in the second trimester and early third trimester, as valve thrombosis has been reported with heparin therapy.10 Warfarin and heparins are safe for use during lactation.20

Bacterial Vaginosis
Bacterial vaginosis is associated with PPROM, chorioamnionitis, preterm birth, and postpartum endometritis.45 Treatment is recommended in all symptomatic women and in asymptomatic women at high risk for preterm delivery, although the treatment has not been shown to reduce the risk of delivery before 37 weeks. The Centers for Disease Control and Prevention (CDC) recommends oral metronidazole or oral clindamycin for the treatment of bacterial vaginosis in pregnant women (see Table 47–7).45

Culture should be performed 1 month after completion of therapy since the cure rate is approximately 70%.45

Vulvovaginal Candidiasis
Only symptomatic vulvovaginal candidiasis should be treated in pregnant or lactating women (see Table 47–7).45

Sexually Transmitted Infections
Table 47–8 presents the management of sexually transmitted infections during pregnancy and lactation, associated risks, and recommended follow-up.45,46 Treatment of all recent sexual partners is mandatory.

Enhancement of Lactation
Optimization of breast-feeding techniques is the first-line strategy for decreased lactation. No drug is currently approved by the FDA for lactation enhancement, but dopamine antagonists, metoclopramide, and domperidone (not available in the United States), which increase prolactin levels are used for this purpose.47 Metoclopramide’s maternal side effects include fatigue, irritability, headache, and extrapyramidal symptoms. Very few side effects in the infant have been reported. Domperidone has been associated with abnormal heart rhythm and sudden cardiac

Patient Encounter, Part 3
At 35 weeks’ gestation, the patient is admitted for preterm labor.

Meds: Lithium 600 mg orally in the morning and at bedtime; quetiapine 100 mg orally at bedtime; levothyroxine 75 mcg orally in the morning; insulin NPH 16 units subcutaneously at bedtime; insulin aspart 20 units subcutaneously before breakfast

Will you recommend a tocolytic agent?
If labor progresses, what special care should be provided?

Patient Encounter, Part 4
After 10 hours of labor, the patient delivers vaginally a 5.6 lb (2.55 kg) baby. She plans to breast-feed.

What treatment plan do you recommend after delivery?
What surveillance do you suggest for the newborn/baby?
Can she breast-feed while taking her medications?

Patient Encounter, Part 2
At 28 weeks of pregnancy, the patient is admitted for acute pyelonephritis and back pain. Blood glucose levels are between 100 and 160 mg/dL (5.6 and 8.9 mmol/L). Urine culture reports the presence of E. coli and group B Streptococcus.

Meds: Lithium 600 mg orally in the morning and at bedtime; quetiapine 100 mg orally at bedtime; levothyroxine 75 mcg orally daily; insulin NPH 10 units subcutaneously at bedtime; insulin aspart 10 units subcutaneously before breakfast

What treatment do you recommend at this time?

*po, orally; PPRM, preterm premature rupture of membranes.

Data from Refs. 45 and 46.*
Patient Care Process

Patient Assessment:
- Complete medical history including obstetrical history.
- Inquire about changes in disorders evolution and last follow-up with the treating physician.
- Conduct medication history (past/current treatments, compliance, efficacy, and safety).
- Verify immunization status.
- Assess for pregnancy signs and symptoms.
- Perform physical examination.
- Evaluate nutritional status and socioeconomic environment.
- Perform first trimester routine lab testing.
- Order serum drug levels.

Therapy Evaluation:
- Evaluate the need for continuing medication (benefits and risks for mother and fetus).
- Assess efficacy, safety, and patient adherence, and screen for drug interactions.
- Evaluate whether safer and more effective alternative medications are available.

Care Plan Development:
- Avoid treatments without evidence of benefit or that can be delayed until after pregnancy and breast-feeding.
- Address patient concerns (risks of medication, risks of relapse if condition is untreated, prescription coverage and access to care).
- Treat pregnancy symptoms (eg, nausea) if they are bothersome or interfering with other pathologies (eg, diabetes).
- When possible, treat pregnancy conditions with nonpharmacologic treatments instead of drug therapy.
- Recommend appropriate folic acid and multivitamins.
- Provide prenatal counseling regarding lifestyle modifications (healthy diet, exercise, avoidance of tobacco, alcohol, and illicit or unnecessary drugs).
- Encourage breast-feeding. If maternal drug therapy is required during breast-feeding, choose drugs with the best safety profile. Communicate information to all other healthcare professionals to ensure continuing of care.

Follow-Up Evaluation:
- Follow up at each prenatal visit or more frequently to assess compliance, effectiveness, and safety of treatment.
- Review and repeat assessments as necessary.
- Monitor infants for birth defects, developmental delays, or unusual reactions, and report suspected drug-related reactions to the FDA or pharmaceutical companies.

REFERENCES

Mastitis
Bacterial mastitis, seen typically within the first 6 weeks of breast-feeding, is characterized by localized signs of inflammation and engorgement. Fever, shivering, and malaise can also occur. The most commonly encountered bacteria are *Staphylococcus aureus* (including methicillin-resistant), followed by *Streptococcus*, *Staphylococcus epidermidis*, and *E. coli*.49
Cold or warm compresses and more frequent breast-feeding or breast pumping, should be encouraged. Antibiotics (see Table 47–7) and analgesics (eg, acetaminophen, NSAIDs) can be used to relieve pain.20,49 If a breast abscess is suspected, ultrasound should be performed before surgical drainage.

Breast Candidiasis
Candidiasis presents with severe and persistent nipple pain, which may throb and radiate to the breasts and back. Pain is usually more intense during and immediately after breast-feeding. The breast-fed infant can be symptomatic or asymptomatic. *Candida albicans* is the most commonly found species. It is recommended to breast-feed more frequently than usual for a shorter period of time. Milk does not have to be discarded; however, clothes and towels in contact with breasts and the baby’s mouth should be washed in hot water. Antifungal treatment must be given to the mother and the baby simultaneously (see Table 47–7). If no improvement is seen within 24 to 48 hours, treatment should be reevaluated. Analgesics (eg, acetaminophen, NSAIDs) can be used.49

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Discuss the physiology of the female reproductive system.
2. Compare the efficacy of oral contraceptives with that of other methods of contraception.
3. State the mechanism of action of hormonal contraceptives.
4. Discuss risks associated with the use of contraceptives, and state absolute and relative contraindications to their use.
5. List side effects associated with the use of various contraceptives, and recommend strategies for minimizing or eliminating such side effects.
6. Describe advantages and disadvantages of various contraceptives, including oral and nonoral formulations.
7. Cite important drug interactions that may occur with oral contraceptives.
8. Provide appropriate patient education regarding the important differences between various barrier methods of contraception.
9. Discuss how emergency contraception may be employed to prevent unintended pregnancy.
10. Provide appropriate patient education regarding the use of oral contraceptives, and recommend and discuss the use of nonoral contraceptives when appropriate.

INTRODUCTION

Historically, the 1950s was an important time in the control of human fertility. It was during that decade that the first combination oral contraceptives (COCs) were developed. Shortly after the discovery that the exogenous administration of hormones such as progesterone successfully blocked ovulation, the use of hormonal steroids quickly became the most popular method of contraception worldwide. COCs are the most commonly used reversible form of contraception in the United States today, with an estimated 10.6 million women users. Studies of women of childbearing age in the United States estimate that 62% are currently using a contraceptive method. Since the introduction of oral contraceptives, many additional contraceptive forms have been developed and are available for use in the United States, including transdermal systems, transvaginal systems, and intrauterine devices (IUDs). These additional forms of contraception offer women effective and potentially more convenient alternatives to oral contraceptives.

EPIDEMIOLOGY

According to the National Survey of Family Growth, approximately 6.58 million pregnancies occur annually in the United States. It is estimated that nearly half of all pregnancies that occur each year in the United States are unintended. Consequently, the risk of unintended pregnancy is the fact that approximately 11% of all women who are at risk of becoming pregnant do not use any form of contraception. In addition, many women who do use contraceptives use their chosen method of contraception imperfectly, and this also increases the risk of unintended pregnancy. For patients with certain medical conditions, such as epilepsy, hypertension, ischemic heart disease, sickle cell disease, lupus, or thromboembolic mutations, unintended pregnancy can further increase the risk for adverse health events. The provision of appropriate and adequate instruction to patients regarding how to use contraceptive methods effectively is essential in order to reduce the risk of unintended pregnancy and, for some women, the associated increase in risk for adverse health-related events.

Exposure to sexually transmitted infections (STIs) is also a concern for women who are sexually active. It is estimated that 20 million people in the United States become newly infected annually with an STI. Given that not all methods of contraception protect the user against STIs, the provision of proper patient education by health care professionals regarding this risk is absolutely essential.

PHYSIOLOGY

The female menstrual cycle is divided into four functional phases: follicular, ovulatory, luteal, and menstrual. The follicular phase begins the cycle, and ovulation generally occurs around day 14. The luteal phase then begins and continues until menstruation occurs. The menstrual cycle is regulated by a negative-feedback
hormone loop between the hypothalamus, anterior pituitary gland, and ovaries.\(^3\) (Figure 48–1).

Initially, the hypothalamus releases gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary to produce follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The levels of FSH and LH released vary depending on the phase of the menstrual cycle. Just prior to ovulation, FSH and LH both are at their peak levels. The FSH helps to promote growth of the follicle in preparation for ovulation by causing granulosa cells lining the follicle to grow and produce estrogen. LH promotes androgen production by theca cells in the follicle, promotes ovulation and oocyte maturation, and converts granulosa cells to cells that secrete progesterone after ovulation.

Conception is most likely to occur when viable sperm are present in the upper region of the reproductive tract at the time of ovulation. Fertilization occurs when a spermatozoan penetrates an ovum. Approximately 6 to 8 days after ovulation, attachment of the early embryo to the lining of the uterine cavity—implantation—occurs.

**PREVENTION OF PREGNANCY:**

**CONTRACEPTIVES AND DEVICES**

**Goals of Contraception/Desired Outcome**

The most common goal of contraception is the prevention of pregnancy. However, some patients use contraceptive methods for other benefits, such as menstrual cycle regulation, reduction of premenstrual symptoms, or treatment of acne.

**Choice of Contraceptives: Important Considerations**

When helping a patient with contraceptive selection, the most important goal is finding an option the patient is comfortable with and the clinician feels is beneficial for the patient. It is imperative to explain the side effects, safety concerns, and noncontraceptive benefits of each alternative to the patient so that she may make an informed decision. Fertility goals vary for each patient. It must be determined whether the goal is to postpone conception, space out the next pregnancy, or avoid...
further pregnancy altogether. Also, a clinician must understand the patient’s desire to have or not have a regular bleeding pattern, because many contraceptives will affect menses.

As discussed later in this chapter, contraindications exist for various forms of contraception. Patients must be evaluated by a health care professional to rule out medical contraindications to certain contraceptives. The physical examination also allows health care professionals to identify other medical concerns, such as hypertension or liver disease, that need to be considered when selecting an appropriate contraceptive agent. Clinicians also should review family history for potential risks with certain forms of birth control.

Sexual behavior of the female must be determined to understand the risk for STIs. Women not in a monogamous relationship must consider their risk of STIs as a factor in their contraceptive decision. Some barrier methods protect against STIs, but hormonal contraceptives do not prevent STIs if used alone.

Personal preference plays a large role when determining the best contraceptive option. For instance, if a woman is not interested in using a method that interrupts sexual activity, then a diaphragm would be an inappropriate choice. Preference of the sexual partner may also be important. Certain agents such as male condoms require the male partner to play an active role in contraception.

Cost may also be an issue for patients. Insurance may not cover all forms of contraception, and patients may have to bear the entire cost for certain options.

Efficacy of Contraceptives

The unintended pregnancy rate for women who do not use any form of contraception is unknown. Therefore, it is difficult to determine the true efficacy of contraceptives in preventing unwanted pregnancy. Table 48–1 shows the percentage of women who experience unintended pregnancy within 1 year of contraceptive use with ongoing sexual activity.1

Oral Contraceptives (Combination)

COCs contain a synthetic estrogen and one of several steroids with progestational activity. Most oral contraceptives contain one of three types of estrogen: ethinyl estradiol (EE), which is pharmacologically active; mestranol, which is converted by the liver to EE; or estradiol valerate, which is metabolized to estradiol and valeric acid. Many different progestins are found in the various oral contraceptives. These include norethindrone, norethindrone acetate, ethynodiol diacetate, norgestrel, levonorgestrel, desogestrel, norgestimate, drospirenone, and Dienogest.

The primary mechanism by which COCs prevent pregnancy is through inhibition of ovulation. FSH and LH regulate the production of estrogen and progesterone by the ovaries. Secretion of estrogen and progesterone by the ovaries occurs in a cyclic manner, which determines the regular hormonal changes that occur in the uterus, vagina, and cervix associated with the menstrual cycle. Cyclic changes in the levels of estrogen and progesterone in the blood, together with FSH and LH, modulate the development of ova and the occurrence of ovulation. The estrogen component of COCs is most active in inhibiting FSH release.3 However, at sufficiently high doses, estrogens also may cause inhibition of LH release. In low-dose COCs, the progestin component causes suppression of LH.4 Ovulation is prevented by this suppression of the midcycle surge of both FSH and LH and mimics the physiologic changes that occur during pregnancy.

Although suppression of FSH and LH is the primary mechanism by which COCs prevent ovulation, there are other mechanisms by which these hormones work to prevent pregnancy.

- Other mechanisms include reduced penetration of the egg by sperm, reduced implantation of fertilized eggs, thickening of

1Among typical couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. Estimates of the probability of pregnancy during the first year of typical use for spermicides, withdrawal, periodic abstinence, the diaphragm, the male condom, the pill, and Depo-Provera are taken from the 1995 National Survey of Family Growth corrected for underreporting of abortion.

2Among couples who initiate use of a method (not necessarily for the first time) and who use it perfectly (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

3Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

- Other mechanisms include reduced penetration of the egg by sperm, reduced implantation of fertilized eggs, thickening of
cervical mucus to prevent sperm penetration into the upper genital tract, and slowed tubal motility, which may delay transport of sperm. Thus, in addition to inhibiting ovulation, COCs induce changes in the cervical mucus and endometrium that make sperm transport and implantation of the embryo unlikely.

Table 48–2 contains a partial listing of the many oral contraceptives available in the United States. Since the mid-1960s, EE has been the primary estrogen used in most COCs. However, the amount of EE used in COCs has decreased progressively since that time, and most now contain 35 mcg or less of EE. In

EE, ethinyl estradiol

<sup>a</sup>Each tablet also contains 451 mcg of levomefolate calcium

<sup>b</sup>Some references may classify as monophasic since the variation in hormone content does not occur during the first three weeks of the pill pack.

addition, to reduce side effects and improve tolerability associated with oral contraceptive use, new progestins and different routes of administration have been explored. In an attempt to minimize the undesirable androgenic side effects associated with the progestins of COCs, the original synthetic progestins were modified to create "third generation" progestins (eg, desogestrel and norgestimate), and newer progestins with antiandrogenic properties (eg, drospirenone) have been discovered. Overall, the synthetic progestins found in today’s COCs are extremely potent in their ability to inhibit ovulation and prevent pregnancy.

COCs are available in monophasic, biphasic, triphasic, and quadruphasic preparations. Monophasic preparations contain fixed doses of estrogen and progestin in each active pill. Although all four preparations contain both estrogens and progestins, biphasic, triphasic, and quadruphasic preparations contain varying proportions of one or both hormones during the pill cycle. These preparations were introduced to reduce a patient’s cumulative exposure to progestins, as well as to mimic more closely the hormonal changes of the menstrual cycle. However, there is no evidence to suggest that the multiphasic preparations offer any significant clinical advantage over monophasic pills.

Most traditional COCs are packaged as 21/7 cycles (ie, 21 days of active pills and 7 days of placebo). However, newer regimens offer either fewer hormone-free days per traditional, 28-day pill cycle or extended (or in some cases continuous) cycles, which may allow for fewer withdrawal bleeds per year and fewer menstrual-related side effects (eg, menstrual pain, bloating, headaches) for some women.

**Noncontraceptive Benefits of Combination Oral Contraceptives**

In addition to preventing pregnancy, there are several noncontraceptive benefits associated with the use of COCs.

**Reduction in the Risk of Endometrial Cancer** The risk of endometrial cancer among women who have used oral contraceptives for at least 1 year is approximately 40% less and for at least 10 years is approximately 80% less than the risk in women who have never used oral contraceptives. There is additional evidence to suggest this benefit is detectable within 1 year of use, and the reduced risk may persist for up to 20 years following discontinuation of oral contraceptives.

**Reduction in the Risk of Ovarian Cancer** When compared with women who have never used oral contraceptives, women who have used oral contraceptives for up to 4 years are 30% less likely to develop ovarian cancer. There is also additional evidence to suggest that the longer the duration of oral contraceptive use, the greater the reduction in the risk of ovarian cancer. Women who have taken oral contraceptives for 5 to 11 years are 60% less likely to develop ovarian cancer, and women who have taken oral contraceptives for more than 12 years are 80% less likely to develop ovarian cancer than those who have never used oral contraceptives. As with the reduced risk of endometrial cancer, there is evidence to suggest the reduced risk of ovarian cancer may persist for years following discontinuation of oral contraceptives.

**Improved Regulation of Menstruation and Reduction in the Risk of Anemia** Women who take oral contraceptives typically experience more regular menstrual cycles. In general, oral contraceptive use is associated with less cramping and dysmenorrhea. Also, women who take oral contraceptives have a smaller volume of menstrual fluid and experience fewer days of menstruation each month and consequently experience less blood loss with each menstrual period. Some studies suggest that oral contraceptive use decreases overall monthly menstrual flow by 60% or more and conserves hemoglobin and ferritin levels, which may be particularly beneficial in women who are anemic or at risk for anemia. In addition, some COC formulations contain iron, which may also minimize the risk for anemia (See Unique Oral Contraceptives section.)

**Reduction in the Risk of Fetal Neural Tube Defects** While COCs are not 100% effective at preventing pregnancy, it is possible that a woman may conceive while taking a COC. In addition, many women may become pregnant very soon after discontinuing a COC. In order to decrease the risk of neural tube defects in the fetuses associated with such pregnancies, COC formulations that contain a source of folate in every pill are also available.

**Relief from Symptoms Associated with Premenstrual Dysphoric Disorder** COCs have been widely used for the treatment of premenstrual dysphoric disorder (PMDD). Current evidence suggests that these agents are most effective at targeting the physical symptoms associated with the disorder and less effective in treating mood-related symptoms. Although multiphasic COCs have been used effectively in the treatment of PMDD, monophasic preparations may yield fewer mood swings and are generally easier to manage. Yaz, which contains the progestin, drospirenone, carries an FDA-approved indication for PMDD.

**Relief of Benign Breast Disease** Women who use oral contraceptives are less likely to develop benign breast cysts or fibroadenomas and are less likely to experience progression of such conditions.

**Prevention of Ovarian Cysts** Because oral contraceptives suppress ovarian stimulation, women who take them are less likely to develop ovarian cysts.

**Decrease in Symptoms Related to Endometriosis** COC use has been linked to a decreased incidence of symptomatic endometriosis. In women who suffer from endometriosis, the extended-cycle COCs may provide the most effective relief from menstrual pain by reducing the total number of painful episodes per year.

**Improvement in Acne Control** All COCs can improve acne by increasing the quantity of sex hormone–binding globulin and thereby decreasing free testosterone concentrations. Third-generation progestins, such as desogestrel and norgestimate, are believed to have less androgenic activity compared with older progestins, and drospirenone is considered to be antiandrogenic. However, it is not clear that COCs containing any of these progestins confer any advantage over other COCs with respect to their ability to improve acne control. Ortho Tri-Cyclen (EE and norgestimate), Estrostep Fe (EE and norethindrone acetate), Yaz, and Beyaz (EE and drospirenone) each carry an FDA-approved indication for the treatment of acne.

**Potential Risks of Combination Oral Contraceptives**

Although there are many noncontraceptive benefits associated with the use of COCs, their use is not without risk or potential for adverse effects.

**Sexually Transmitted Infections** Because the use of COCs may decrease the use of selected barrier contraceptive methods (eg, latex condoms) that do protect against STIs, one of the most common potential risks associated with the use of oral contraceptives is the increased risk of acquiring an STI.

**Cardiovascular Events and Hypertension** A World Health Organization (WHO) collaborative study found that high-dose
(50 mcg or more of EE) oral contraceptive users with uncontrolled hypertension have an increased risk of experiencing a myocardial infarction or stroke. In this study, women who had the lowest risk for experiencing a myocardial infarction or stroke were those who did not smoke, took low-dose oral contraceptives, and had their blood pressure checked prior to beginning oral contraceptives. Hypertension secondary to oral contraceptive use is thought to occur in up to 3% of women and is believed to be attributed to the effect that estrogens and progestins can have on aldosterone activity. Given this and the risk for cardiovascular events, women should have their blood pressure checked prior to initiating oral contraceptives, as well as periodically throughout oral contraceptive use. If significant elevations in blood pressure are noted, oral contraceptives should be discontinued. Estrogen-containing contraceptives are not recommended for smokers who are 35 years of age or older, for women with hypertension (especially if untreated), or for women who experience migraine headaches (especially those with focal neurologic symptoms).

**Venous Thromboembolism** It is believed that the estrogen component of COCs stimulates enhanced hepatic production of clotting factors. COCs have been associated with a twoto three-fold increase in the risk of venous thromboembolism compared with women who do not use oral contraceptives. Contraceptive users at greatest risk for the development of venous thromboembolism include those who are obese, smoke, have hypertension, have diabetes complicated by end-organ damage, are immobile, have experienced recent trauma or surgery, or have a history of prior thromboembolism. It is important to note, however, that the increase in risk of venous thromboembolism in oral contraceptive users is lower than that associated with pregnancy and the postpartum period. Newer, less androgenic progestins, such as desogestrel and drospirenone, have been reported to be associated with a higher risk of venous thromboembolism. Currently available studies validating this risk have produced conflicting results. Two studies published in 2011 reported a two- to three-fold greater risk of venous thromboembolic events in women using oral contraceptives containing drospirenone when compared with women using levonorgestrel-containing contraceptives. However, the results of the International Active Surveillance Study of Women Taking Oral Contraceptives, published in 2014, demonstrated similar rates of venous and arterial thromboembolism in women taking COCs containing drospirenone, levonorgestrel, or other progestins. In general, progestin-only contraceptives are preferred for women who are at increased risk of cardiovascular or thromboembolic complications, including women with a prior history of thromboembolic disease.

**Gallbladder Disease** In women with preexisting gallstones, low-dose estrogen-containing oral contraceptives may enhance the potential for the development of symptomatic gallbladder disease and may worsen existing gallbladder disease. Although this risk has not been demonstrated with the use of higher-dose oral contraceptives, COCs containing estrogen should be used with caution in patients with a history of gallbladder disease.

**Hepatic Tumors** Although the use of oral contraceptives is not associated with an increased risk for the development of hepatocellular carcinoma, long-term use of high-dose oral contraceptives has been associated with the development of benign liver tumors. Because even benign liver tumors may pose significant risk to the patient, oral contraceptives should be discontinued if liver enlargement is noted on physical examination. In cases of hepatoma (malignancy), the use of COCs is contraindicated. In women who have a history of gallbladder disease, COCs containing estrogen should be used with caution in patients with a history of gallbladder disease.

**Cervical Cancer** There appears to be an increased risk for the development of cervical cancer among long-term users of oral contraceptives. It is uncertain whether this increase in risk is directly attributed to the use of oral contraceptives. Data suggest that oral contraceptive users tend to have more sexual partners and use condoms less frequently, and as a result, this may increase their susceptibility to infection with human papilloma virus (HPV), a known risk factor for cervical cancer.

**Adverse Effects of Oral Contraceptives and Their Management**

As with all medications, there are potential adverse effects with COCs. Many side effects can be minimized or avoided by adjusting the estrogen and/or progestin content of the oral contraceptive. It is also important to individualize the selection of oral contraceptives, because some women are at increased risk for potentially serious side effects.

Common complaints with COCs include headaches, nausea, vomiting, mastalgia, and weight gain; although studies have shown a similar percentage of patients taking placebo experience these side effects. Given that oral contraceptives often are discontinued owing to side effects, proper counseling before initiation of COCs is necessary.

Between 30% and 50% of women complain of breakthrough bleeding or spotting when oral contraceptives are initiated. These side effects tend to resolve by the third or fourth cycle. Before changing formulations, other more serious causes of bleeding or spotting, such as pregnancy, infection, and poor absorption of the oral contraceptive owing to drug interaction or GI problems, should be ruled out. Once these causes have been ruled out, the timing of the spotting must be determined in order to adjust the formulation appropriately.

---

**Patient Encounter, Part 1**

A 22-year-old nulliparous woman, presents to your clinic requesting information on contraception. She specifically inquires about options that allow for fewer or no menstrual periods. You begin to take a history and determine that the patient is currently sexually active and is not using any method of birth control. She weighs 135 lb (61.4 kg), is 64 in (163 cm) tall, and has a blood pressure of 108/70 mm Hg. She has no history of smoking. She has migraines without aura, for which she takes propranolol. On further questioning, you discover that she has a positive family history of breast cancer (both her mother and maternal aunt), but no personal history. As you discuss various contraceptive options with the patient, it is clear that she has a preference for an oral contraceptive agent.

**What additional information do you need to know before recommending a contraceptive for this patient?**

**Based on the information provided by the patient, what oral contraceptive agent would you recommend for the patient and why?**

**What education would you provide to this patient regarding risks associated with oral contraceptive use?**
The most common side effects and ways to adjust therapy to minimize these side effects are listed in Table 48–4.1,3,6,27,28 As highlighted in Table 48–4, many of the side effects of COCs may be minimized by adjusting the estrogen or progestin content of the preparation. However, although low-dose COCs may cause fewer side effects, it is important to note that in the event that doses are missed, such COCs may be more likely to result in contraceptive failure.

Data from Refs. 3, 4, and 25.

* Progestin-Only Pills
  - For women unable to take estrogen-containing oral contraceptives, there is an alternative: oral contraceptives containing only the progestin, norethindrone. These agents are slightly less effective than COCs but have other advantages over COCs.
  - Progestin-only products have not shown the same thromboembolic risk as estrogen-containing products. Therefore, women at increased risk for or with a history of thromboembolism may be good candidates for progestin-only oral contraceptives. Also, these products can minimize menses, and many women have amenorrhea after six to nine cycles. These products have also been found safe to use in women who are nursing, so they are a viable option for women who breast-feed and desire hormonal contraception. In such patients, it should not be initiated until 6 weeks postpartum. Spotting does not subside in some women, and this is a common cause for discontinuation. These products should be taken at the same time every day, and there is no pill-free or hormone-free period.

* Unique Oral Contraceptives
  - Along with varying doses of estrogen and different progestins, there are also formulation modifications that may benefit various patient situations. In the United States, these formulations include products such as Lo-Loestrin Fe; Amethia, Camrese, Daysee, Introvale, and Seasonale; Amethia Lo and Camrese Lo; Seasonique and Lo Seasonique; Yasmin, Yaz, and Beyaz; Ortho Tri-Cyclen and Estrostep Fe; Kariva, Micrette, Pimtrea, and Viorele; Ovcon 35; Lybrel; Natazia; and Quartette. Each of these products may show benefit in certain women owing to their unique characteristics.
    - Lo-Loestrin Fe (norethindrone/EE) contains a low-dose estrogen, a high amount of progestin, and medium androgenic activity. Similar to other low-dose estrogen COCs, Lo-Loestrin Fe may offer a smaller margin of error when pills are missed but provide the potential advantage of fewer estrogen-related side effects (eg, nausea and breast tenderness). Unlike the typical 28-pill packs that contain 21 active tablets and seven placebo tablets, Lo-Loestrin Fe contains 24 combination hormone tablets, two estrogen-only tablets, and two placebo (iron-only) tablets. This product provides a shorter hormone-free interval and may allow for shorter menstrual periods and fewer menstrual-related symptoms, such as menstrual-related headaches, menorrhagia, and anemia.
    - Amethia, Camrese, Daysee, Introvale, Jolessa, and Seasonale, (levonorgestrel/EE) are each monophasic combinations that are packaged as a 91-day treatment cycles with 84 active tablets that are taken consecutively followed by seven placebo tablets. The extended cycle length of these products allows for one menstrual cycle per “season,” or four per year. This type of formulation may be appealing to women with perimenstrual side effects or those at higher risk for anemia with menstrual bleeding. These products may improve anxiety, headache, fluid retention, dysmenorrhea, breast tenderness, bloating, and menstrual migraines. However, in the SEA 301 clinical trial comparing the efficacy of Seasonale with that of an equivalent-dosage 28-day cycle regimen, 7.7% versus 1.8% of women discontinued prematurely for unacceptable bleeding.30 The risk of intermenstrual bleeding and/or spotting may be higher for patients taking these extended-cycle combinations than for patients taking typical 28-day-regimen COCs.
    - Seasonique and Lo Seasonique (levonorgestrel/EE) are also extended cycle preparations that are similar to those mentioned earlier, but instead these preparations contain seven tablets with low-dose estrogen rather than placebo. Menstruation-related problems that may improve with Seasonique or Lo Seasonique include menstrual-related headaches, menorrhagia, and anemia. In addition, endometriosis-related menstrual pain may be relieved by providing a continuous regimen without a pill-free interval.31
    - Yasmin and Yaz (drospirenone/EE) are unique oral contraceptives that contain the progestin drospirenone. This hormone not only has antiandrogenic properties, but also showed antimineralocorticoid activity in preclinical trials. It has a unique application in young women who experience problems associated with producing too much androgen. Drospirenone is a spironolactone analog, and the 3-mg dose available in COC preparations has antimineralocorticoid activity equal to 25 mg of spironolactone. It can affect the sodium and water balance in the body, although it has not shown superior efficacy for side

</tbody>
</table>

Data from Refs. 1, 3, 6, and 27–29.

Effects such as bloating compared with other oral contraceptives. Caution should be used in women with chronic conditions or in women taking other medications that may affect serum potassium. Yaz (drospirenone/EE) is an extended-cycle preparation that contains a low-dose estrogen and antimineralocorticoid and antiandrogenic activity. Yaz also contains 24 rather than 21 active tablets and four rather than seven placebo tablets, allowing for shorter menstrual periods and fewer menstrual-related symptoms, such as menstrual-related headaches, menorrhagia, and anemia.

In 2003, the FDA Advisory Committee for Reproductive Health Drugs recommended the development of a COC tablet containing folic acid in order to minimize the risk of neural tube defects in cases of contraceptive failure. Beyaz and Safyral, which
were FDA approved in 2010, are combination tablets containing drospirenone and EE (like Yaz and Yasmin) and 451 mcg of levomefolate calcium, the primary metabolite of folic acid. Similar to Yaz, Beyaz is an extended-cycle preparation, which may allow for shorter menstrual periods and fewer menstrual-related symptoms.

In addition to the prevention of pregnancy, Yaz, Beyaz, Ortho Tri-Cyclen (noregestimete/EE), and Estrostep Fe (norethindrone acetate/EE) each carry an approved indication for treatment of moderate acne vulgaris in females 15 years of age or older desiring contraception who have not responded adequately to conventional antiandrogen medication. This can help clinicians to streamline medications by serving dual purposes.

Mircette, Kariva, Pimtrex, and Viorele (desogestrel/EE) have a unique dosing schedule. After the usual 21 active tablets, there are only two tablets with inert ingredients. The last five tablets in the package have 10 mcg of EE. In theory, this may minimize bleeding during the menstrual cycle, although the clinical significance of this dosing schedule has not been established. With each of these products, it is important to counsel patients to complete the entire pack and not to discard the last 7 days of medication.

Another unique formulation is a chewable tablet available to women who have difficulty swallowing medications. Ovcon 35 (norethindrone/EE) has all 28 tablets in chewable form and has added spearmint flavoring.

Lybrel (levonorgestrel/EE) was the first continuous-cycle COC approved by the FDA. Active pills are taken every day throughout the year with no pill-free interval. The major advantage of this product is elimination of menstrual periods, resulting in improvement in or elimination of menstrual-related symptoms. The most bothersome side effect associated with Lybrel is a high incidence of spotting and breakthrough bleeding during the initial months of use. It appears as though the incidence of breakthrough bleeding with Lybrel decreases with continued use.

Natazia was approved by the FDA in 2010 and is a quadrphasic COC containing estradiol valerate and the progestin, dieno
gest. Estradiol valerate is metabolized endogenously to estradiol, and dieno
gest is a strong progestin with antiandrogenic activity.

Natazia provides a unique estrogen step-down/progestin step-up regimen, and like Mircette, Kariva, Pimtrex, and Viorele, this COC offers the advantage of a shorter hormone-free interval. This results in fewer days of withdrawal bleeding and may help with menstrual-related headaches.

Finally, Quartette (levonorgestrel/EE), an extended-cycle, quadvphasic preparation approved by the FDA in 2013, contains increasing doses of EE throughout the 91-day pill period. The increasing dose of EE is intended to reduce the rate of breakthrough bleeding or spotting.

**Drug Interactions with Oral Contraceptives**

EE is metabolized in the liver primarily via cytochrome P-450 (CYP450) 3A4. When reviewing drug interactions of oral contraceptives, clinicians should be aware of the many drugs that may potentially interact with contraceptives—especially those that may reduce the effectiveness of contraceptives. Refer to Table 48–5 for a list of some of the most common drug interactions seen with oral contraceptives.3,32,33

**Nonoral Hormonal Contraceptives**

As an alternative to oral contraceptive pills, which must be taken daily in order to reliably prevent pregnancy, non-
oral contraceptives in the form of transdermal, transvaginal, and injectable preparations are available and offer patients safe and effective alternatives to the pills for prevention of pregnancy. These formulations also do not require daily administration, making them more convenient than the pill formulations.

Ortho-Evra is a transdermal patch that contains both an estrogen (20 mcg of EE) and a progestin (150 mcg of norelgestromin). A new patch is applied to the abdomen, buttocks, upper torso, or upper (outer) arm once weekly for 3 weeks, followed by seven patch-free days.6 Although some women have noted irregular bleeding during the first two cycles of patch use, the patch has been demonstrated to provide similar menstrual cycle control and contraceptive efficacy to that of COCs.34 It is important to note, however, that higher contraceptive failure rates are seen when the patch is used in women weighing more than 90 kg (about 200 lb).6,34 Further, manufacturer prescriber information indicates that women who take Ortho-Evra are exposed to approximately 60% more estrogen than women who take COCs with 35 mcg of estrogen.35 Although the clinical significance of this is not well defined, studies have suggested a link between the use of the patch and an increased risk for venous thromboembo-
lism. A slightly higher reported incidence of breast discomfort and local skin irritation has also been reported with the patch.6,36

NuvaRing is a unique transvaginal delivery system that provides 15 mcg of EE and 120 mcg of etonogestrel for the preven-
tion of ovulation. NuvaRing is inserted into the vagina on or before day 5 of the menstrual cycle and is removed from the vagina 3 weeks later.6 Seven days after the ring is removed, a new ring should be inserted. In clinical trials, NuvaRing demonstrated comparable efficacy and cycle control to COCs as well as a similar side-effect profile.6,37 NuvaRing should not be removed during intercourse.

Depo-Provera is a progestin-only, injectable contraceptive that contains depot medroxyprogesterone acetate. Depo-Provera is administered intramuscularly as a 150-mg injection once every 3 months. An advantage of Depo-Provera is that it provides an estrogen-free method of contraception either for women in whom estrogens are contraindicated or for women who cannot tolerate estrogen-containing preparations. Depo-Provera is extremely effective in preventing pregnancy. However, the incidence of menstrual irregularities (including amenorrhea) and weight gain appears to be much greater than that seen with COCs. The use of Depo-Provera also has been demonstrated to result in significant loss of bone mineral density (BMD).38 Although the effect is known to be reversible following product discontinuation, a black-box warning within the product label-
ing cautions against the risk of potentially irreversible BMD loss.

---

**Patient Encounter, Part 2: Adverse Effects**

After 3 months of taking LoSeasonique, she returns to your clinic complaining of breakthrough bleeding during her sixth week of active pills. She reports no change or increase in frequency of her migraine headaches, and her blood pressure is 110/72 mm Hg. She is frustrated with the breakthrough bleeding and wants to explore other contraceptive options.

**What are some potential causes of the breakthrough bleeding that the patient has been experiencing?**

**What strategy would you recommend to eliminate or minimize the potential adverse effects experienced by the patient?**
Table 48–5

Commonly Seen Drug Interactions With COCs

<table>

*Although package inserts warn of this potential interaction, no scientific literature exists to support that concomitant antibiotics and COCs is associated with contraceptive failure.*

Data from Refs. 1, 32, and 33.

Associated with long-term use (eg, greater than 2 years) of the injectable product. Although the extended duration of activity of this product may offer women the advantage of less frequent administration, it is important to note that on discontinuation of Depo-Provera, the return of fertility can be delayed by approximately 10 to 12 months (range 4–31 months). Depo-SubQ Provera 104 is also an injectable contraceptive product that contains only progestin (depot medroxyprogesterone acetate). This product differs from Depo-Provera in that it is given subcutaneously rather than intramuscularly, and it contains only 104 mg of medroxyprogesterone acetate (~30% less hormone) administered every 3 months for the prevention of pregnancy. Clinical trials have demonstrated that the subcutaneous formulation of depot medroxyprogesterone acetate is as effective as the intramuscular formulation in the prevention of pregnancy. This product carries the same warning in its package labeling regarding possible effects on BMD as Depo-Provera.

Long-Acting Reversible Contraception

The currently available products for long-term reversible contraception (LARC) are listed in Table 48–6. Surveys have shown that LARC has the highest satisfaction rate among patients using reversible contraceptives, and use within the United States is on the rise.

Although the mechanism of action for IUDs is not completely understood, several theories have been suggested. The original theory is that the presence of a foreign body in the uterus causes an inflammatory response that interferes with implantation. It is believed that copper-containing IUDs may interfere with sperm transport and fertilization and prevent implantation. Progestin-containing implantable contraceptives can have direct effects on the uterus, such as thickening of cervical mucus and alterations to the endometrial lining. Paragard T 380A does not prevent ovulation, although the other LARCs can because they are progestin-containing products.
It is important to evaluate a patient to determine whether she is an appropriate candidate for an implantable contraceptive. IUDs are recommended for women who are in a monogamous relationship, are at low risk for acquiring STIs, have no history of pelvic inflammatory disease (PID), and no history or risk of ectopic pregnancy. Contraindications to the use of progestin-containing LARC products include (a) known or suspected pregnancy, (b) hepatic tumors or active liver disease, (c) undiagnosed abnormal genital bleeding, (d) known or suspected carcinoma of the breast or personal history of breast cancer, (e) history of thrombosis or thromboembolic disorders, and (f) hypersensitivity to any components of the products. There are also multiple additional contraindications to IUD use. Evaluation of the patient is essential because IUDs cannot be used in the following situations: (a) anatomically abnormal or distorted uterine cavity, (b) acute PID or history of PID unless there has been a subsequent intrauterine pregnancy (c) postpartum endometritis or infected abortion in the past 3 months, (d) known or suspected uterine or cervical malignancy, (e) untreated acute cervicitis, (f) previously inserted IUD still in place, (g) increased susceptibility to pelvic infections, and (h) Wilson disease (Paragard T 380A only).

The most common adverse effects are abdominal/pelvic cramping, abnormal uterine bleeding, and expulsion of the device. Other side effects seen are ectopic pregnancy, sepsis, PID, embedment of the device, uterine or cervical perforation, and ovarian cysts.

**Nonpharmacologic Contraceptive Methods**

**Barrier Contraceptives**

As an alternative to hormonal contraceptives, several barrier contraceptive options are available for the prevention of pregnancy. Although barrier contraceptives are associated with far fewer adverse effects compared with hormonal contraceptives, their efficacy is highly user-dependent. Overall, compared with both hormonal contraceptives and IUDs, barrier contraceptives are associated with much higher unintended pregnancy rates (see Table 48–1).

**Diaphragms and Cervical Caps**

Diaphragms and cervical caps are dome-shaped rubber caps that are placed over the cervix to provide barrier protection during intercourse. Both diaphragms and cervical caps require fitting by a health care professional, and they must be refitted in the event of weight gain or weight loss. Diaphragms or cervical caps typically can be placed over the cervix as much as 6 hours prior to intercourse. They must be left in place for at least 6 hours after intercourse before they can be removed. Diaphragms should not be left in place longer than 24 hours, and smaller cervical caps should not be left in place longer than 48 hours owing to the risk of toxic shock syndrome (TSS). Diaphragms and cervical caps are used along with spermicides to prevent pregnancy. When sexual intercourse is repeated with the diaphragm, reaplication of the spermicide is necessary. However, when sexual intercourse is repeated with a cervical cap, reaplication of the spermicide typically is not necessary. Whether or not diaphragms or cervical caps provide adequate protection against STIs remains unclear.

**Spermicides**

Nonoxynol-9, a surfactant that destroys the cell membranes of sperm, is the most commonly used spermicide in the United States. Nonoxynol-9 is available in a variety of forms, including a cream, foam, film, gel, suppository, and tablet. Spermicides may be used alone, with a barrier method, or adjunctively with other forms of contraceptives to provide additional protection against unwanted pregnancy. To be used most effectively, spermicides must be placed in the vagina not more than 1 hour prior to sexual intercourse, and they must come in contact with the cervix. Although the efficacy of spermicides depends largely on how consistently and correctly they are used, their efficacy is enhanced when they are used in combination with a barrier contraceptive device. Clinical trials assessing the ability of spermicides to protect against STIs have failed to produce positive results. Further, there exists some evidence to suggest that frequent use of spermicides actually may increase risk for acquisition of human immunodeficiency virus (HIV) secondary to vaginal mucosal tissue breakdown, which may allow a portal of entry for the virus. In December 2007, the FDA issued a statement requiring manufacturers of nonoxynol-9 products to include a warning on the product label indicating that the spermicide does not provide protection against infection from HIV or other STIs.

**Condoms**

Condoms, which are available for both male and female use, act as physical barriers to prevent sperm from coming into contact with ova. Condoms are easy to use, available without a prescription, and inexpensive. Most condoms are made of latex. When used correctly, condoms can be very effective in prevention of unwanted pregnancy. Condoms should be stored in a cool, dry place, away from exposure to direct sunlight. When stored improperly or when used with oil-based lubricants, however, latex condoms can break during intercourse, increasing the risk of pregnancy. For latex-sensitive individuals, condoms made from lamb intestine (“natural membrane” condoms) and synthetic polyurethane condoms are available. Unlike latex condoms, condoms made from lamb intestine contain small pores that may permit the passage of viruses and therefore do not provide adequate protection against STIs. **KEY CONCEPT Both latex and synthetic condoms can provide some protection against many STIs. Data from one meta-analysis suggested that HIV transmission can be reduced by as much as 90% when condoms are consistently used. This is in contrast to hormonal contraceptives (oral, transdermal, or vaginal), IUDs, and most other barrier contraceptives, which do not protect against STIs.** Relative to male condoms,
female condoms may offer even better protection against STIs because they provide more extensive barrier coverage of external genitalia, including the labia and the base of the penis. It is important to note that the male and female condoms are not recommended to be used together because they may adhere to one another, causing displacement of one or both condoms.

**Sponge**  The Today sponge is a small, pillow-shaped polyurethane sponge impregnated with nonoxynol-9. It is an over-the-counter barrier contraceptive that has been shown to be generally less effective at preventing pregnancy than diaphragms. The sponge is moistened with water and then is inserted and placed over the cervix for up to 6 hours prior to sexual intercourse. The sponge then is left in place for at least 6 hours following intercourse. Although the sponge maintains efficacy for 24 hours (even if intercourse is repeated), as with diaphragms, the sponge should be removed after 24 hours owing to the risk of TSS.

**Fertility Awareness-Based Methods**  Fertility awareness–based methods (natural methods) represent another nonpharmacologic means of pregnancy prevention. Although failure rates of such methods can be high, some couples still prefer these types of approaches. Fertility awareness–based methods depend on the ability of the couple to identify the woman’s “fertile window,” or the period of time in which pregnancy is most likely to occur as a result of sexual intercourse. During the fertile window, the couple practices abstinence, or avoidance of intercourse, in order to prevent pregnancy. In some cases, rather than practicing abstinence during the fertile period, some couples may prefer to employ barrier methods or spermicides as a means of preventing pregnancy rather than to avoid intercourse altogether. In order to identify the fertile window, a number of different fertility awareness–based methods may be tried. The calendar (rhythm) method involves counting the days in the menstrual cycle and then using a mathematical equation to determine the fertile window. The temperature method involves monitoring changes in the woman’s basal body temperature using a basal thermometer. The cervical mucus (or Billings ovulation) method involves observing changes in the characteristics of cervical secretions throughout the cycle. Around ovulation, the mucus becomes watery. The symptothermal method, which is considered to be the most difficult to learn but potentially the most effective, is a combination of both the temperature method and the cervical mucus method. In general, fertility awareness–based methods are not recommended for women who have irregular menstrual cycles or who have difficulty interpreting their fertility signs correctly.

**Emergency Contraception**  Emergency contraception (EC) is used to prevent pregnancy after known or suspected unprotected sexual intercourse. There are five FDA-approved oral agents available for use as EC, with availability from over the counter to prescription only access. The product known as ella (ulipristal acetate), a progestrone-receptor agonist/antagonist, can delay follicular rupture if taken just before ovulation and may cause endometrial changes to interfere with implantation. The available products are listed in the Table 48–7 along with information on availability and correct dosage. It is important to note that EC is more effective the earlier it is used after unprotected intercourse. Common side effects include headache, nausea, abdominal pain, dysmenorrhea, fatigue, and dizziness. If severe abdominal pain occurs, patients should be referred to their health care provider for evaluation of risk of an ectopic pregnancy. Patients should also contact their health care provider if their menstrual cycle is more than 1 week late after taking EC.
Patient Assessment:
- Determine goals related to contraceptive use (pregnancy prevention, menstrual regulation, control of acne?).
- Based on physical exam findings, as well as medical, social (i.e., smoking) and family history, determine if patient qualifies for hormonal contraceptives. Rule out pregnancy, and evaluate patient’s risk for STIs.
- Conduct thorough medication history to identify potential for drug interactions.

Therapy Evaluation:
- At follow-up visits, assess blood pressure, weight, and menstrual patterns for changes from baseline.
- Assess tolerability of and adherence to the prescribed contraceptive method.
- Assess safety by using the pneumonics, “ACHES” for hormonal contraceptives, and “PAINS” for IUDs:
  ACHES -
  A = Abdominal pain
  C = Chest pain
  H = Headaches (especially if associated with focal neurologic symptoms)
  E = Eye problems (blurred vision, ocular pain, visual changes)
  S = Severe leg pain
- Also monitor for missed periods, signs of pregnancy, appearance of jaundice, and/or severe mood changes.

PAINS -
  P = Period late
  A = Abdominal pain, pain with intercourse
  I = Infection, abnormal/odorous vaginal discharge
  N = Not feeling well, fever, chills
  S = String (missing, shorter, longer)

Care Plan Development:
- Select a contraceptive option that the patient is comfortable with, that is likely to achieve the patient’s desired goal(s), and is not contraindicated.
- Educate regarding the potential for side effects, safety risks, drug interactions, and any noncontraceptive benefits that may result for the chosen method.
- Determine the patient’s sexual behavior and evaluate whether the contraceptive method will impact the risk for STIs.
- Evaluate insurance coverage/cost factors.

Follow-up Evaluation:
- Instruct the patient to consult a health care professional upon noticing or experiencing any warning signs.
- Stress the importance of adherence (especially if prevention of pregnancy is desired).
- Educate on what to do in the event of missed doses.

OUTCOME EVALUATION
Side effects of contraceptives tend to occur in the first few months of therapy. Thus schedule a follow-up visit 3 to 6 months after initiating a new contraceptive. Yearly checkups usually are sufficient for patients who are doing well on a particular product. At each follow-up visit, assess blood pressure, headache frequency, and menstrual bleeding patterns, as well as compliance with the prescribed regimen. Strict adherence to the prescribed hormonal contraceptive regimen is essential for effective prevention of unintended pregnancy. When a contraceptive dose is missed, the risk of accidental pregnancy may be increased. Depending on how many doses were missed, the contraceptive formulation being used, and the phase of the cycle during which doses were missed, counseling regarding the use of additional methods of contraception may be warranted.

Abbreviations Introduced in This Chapter
- BMD = Bone mineral density
- COC = Combined oral contraceptive
- CYP450 = Cytochrome P-450
- EC = Emergency contraception
- EE = Ethinyl estradiol
- FSH = Follicle-stimulating hormone
- GnRH = Gonadotropin-releasing hormone
- HIV = Human immunodeficiency virus
- HPV = Human papilloma virus
- IUD = Intrauterine device
- LARC = Long-acting reversible contraception
- LH = Luteinizing hormone
- PID = Pelvic inflammatory disease
- PMDD = Premenstrual dysphoric disorder
- STI = Sexually transmitted infection
- TSS = Toxic shock syndrome
- WHO = World Health Organization

REFERENCES
LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the underlying etiology and pathophysiology of dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia and how they relate to selecting effective treatment modalities.

2. Describe the clinical presentation of dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.

3. Recommend appropriate nonpharmacologic and pharmacologic interventions for patients with dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.

4. Identify the desired therapeutic outcomes for patients with dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.

5. Design a monitoring plan to assess the effectiveness and adverse effects of pharmacotherapy for dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia.

INTRODUCTION

The most common menstruation-related disorders include dysmenorrhea, amenorrhea, anovulatory bleeding, and menorrhagia. These disorders negatively affect quality of life, reproductive health, work productivity, and may lead to adverse long-term health consequences, such as osteoporosis or polycystic ovarian syndrome.

DYSMENORRHEA

Dysmenorrhea is pelvic pain, generally described as cramping, that occurs during or just prior to menstruation. Primary dysmenorrhea is pain in the setting of normal pelvic anatomy and physiology, whereas secondary dysmenorrhea is associated with underlying pelvic pathology.

Epidemiology and Etiology

Rates of dysmenorrhea range from 16% to 90%. Around 8% to 15% percent of women with dysmenorrhea report limited daily activities or missed days in work or school. Risk factors for dysmenorrhea include irregular or heavy menses, age less than 30, menarche prior to age 12, body mass index (BMI) less than 20 kg/m², history of sterilization or sexual abuse, and smoking. Causes of secondary dysmenorrhea may include endometriosis, pelvic inflammatory disease, uterine or cervical polyps, and uterine fibroids.

Pathophysiology

In primary dysmenorrhea, elevated arachidonic acid levels in the menstrual fluid lead to increased concentrations of prostaglandins and leukotrienes in the uterus. This induces uterine contractions, stimulating pain fibers, reducing uterine blood flow, and causing uterine hypoxia.

Treatment

Desired Outcomes

Desired treatment outcomes (Figure 49–1) are relief of pelvic pain, improved quality of life, and fewer lost days at school and work.

Nonpharmacologic Therapy

Nonpharmacologic interventions which diminish dysmenorrhea symptoms include topical heat therapy, regular exercise, transcutaneous electric nerve stimulation (TENS), and acupuncture. In addition, a low-fat vegetarian diet has been shown to lessen the intensity and duration of dysmenorrhea.

Pharmacologic Therapy

Medication management options are summarized in Table 49–1. NSAIDs are the treatment of choice for dysmenorrhea. By inhibiting prostaglandin production, they exert analgesic properties, decrease uterine contractions, and reduce menstrual blood flow. Choice of one agent over another is based on cost, convenience, and patient preference. Most commonly used agents are naproxen and ibuprofen.

Treatment with an NSAID should begin 1 to 2 days prior to the start of menses or at the onset of dysmenorrhea and continued for 2 to 3 days or until pain resolves. A loading dose (twice the usual single dose) is recommended, followed by the usually recommended dose. For patients in whom NSAIDs are contraindicated, combination hormonal contraceptives should be considered.

Combination Hormonal Contraceptives (CHCs) CHCs improve mild to severe dysmenorrhea by inhibiting the
Patient Encounter 1, Part 1

A 22-year-old white woman presents to her physician reporting severe pelvic pain and cramping during menses that results in 1 to 2 missed work days each menstrual cycle. Her last menstrual cycle was 9 days ago, and she had her first menstrual cycle at age 11. She is sexually active with one partner and has had 5 sexual partners in the past. Of note, she has a history of Chlamydia in the past. She has been using acetaminophen or ibuprofen as needed for pain and is a current smoker. She does not follow a diet or exercise regimen.

What risk factors does this patient have for primary dysmenorrhea?

What risk factors does the patient have for secondary dysmenorrhea?

proliferation of endometrial tissue and ovulation, thereby reducing prostaglandin secretion and menstrual blood volume.1,3–5 Two to three months of therapy are required to achieve the full effect.1 Both standard (28-day) and extended cycle (91-day) therapies are effective for primary dysmenorrhea.1,2 Extended cycle regimens are considered first line for dysmenorrhea due to endometriosis.2 Additional benefits include contraception and improving acne.3 Although monophasic formulations are purported to be more efficacious for this indication, evidence supporting this is limited.16 If no response occurs after 3 months of therapy, the patient should be evaluated for secondary causes.1,5

Progestin-only Hormonal Contraceptives These agents diminish dysmenorrhea by reducing or eliminating menses over time, thus eliminating prostaglandin release.3 Three agents are available: depot medroxyprogesterone acetate, etonogestrel implant, and levonorgestrel-releasing intrauterine system. Observational data show a reduction in dysmenorrhea from 60% to 29% with levonorgestrel-releasing intrauterine device (IUD) therapy for 3 years.5 Although data are limited, this is an option for dysmenorrhea management.16

Dysmenorrhea in Adolescents

Dysmenorrhea is reported in 60% to 90% of adolescent females.1 It is the most common reason for adolescents to miss school or work. One study showed that most young females are treating pelvic pain with nonpharmacologic therapies, while other studies showed that many either do not know to use NSAIDs or use subtherapeutic doses.5 Treatment in adolescents includes any of the therapies previously discussed. Although NSAIDs and oral CHCs are most common, levonorgestrel IUD use is also an option.16

AMENORRHEA

Amenorrhea is the absence of menses. Primary amenorrhea occurs prior to age 15 in the presence of normal secondary sexual development or within 5 years of thelarche (if occurring before age 10).1,9,20 Secondary amenorrhea is the absence of menses for three cycles or 6 months in a previously menstruating woman.4

CEE, conjugated equine estrogen; CHC, combination hormonal contraceptive; HDL, high-density lipoprotein; IUD, intrauterine device; LDL, low-density lipoprotein.

³Use is contraindicated in patients with severe hepatic impairment.

⁴Not recommended in patients with severe renal impairment.

⁵Use is contraindicated with creatinine clearance less than 30 mL/min (0.5 mL/s).

⁶Contraindicated in males with serum creatinine more than 1.5 mg/dL (133 μmol/L); females with serum creatinine more than 1.4 mg/dL (124 μmol/L); caution with creatinine clearance less than 60 mL/min (1 mL/s).

⁷Contraindicated in patients with active liver disease or if transaminases more than 2.5 times upper limit of normal at baseline, discontinue therapy if ALT is more than three times upper limit of normal.

Data from Refs. 1, 2, 5–15, 44, 45.

---

### Epidemiology and Etiology

**KEY CONCEPT** Unrecognized pregnancy is the most common cause of amenorrhea, therefore, a urine pregnancy test should be one of the first steps in evaluating amenorrhea. Amenorrhea not related to pregnancy, lactation, or menopause occurs in 3% to 4% of women. Additional causes of secondary amenorrhea include polycystic ovarian syndrome (PCOS), hypothalamic suppression, hyperprolactinemia, or primary ovarian insufficiency.

### Pathophysiology

In the diagnosis and management of amenorrhea, the uterus, ovaries, anterior pituitary, and hypothalamus should be considered (Figure 49–2). Normal menstrual cycle physiology depends on hormonal interactions involving the hypothalamus, anterior pituitary gland, ovary, and endometrium (Figure 49–3). Table 49–2 shows causative condition(s) and the organ system(s) involved in the pathophysiology of amenorrhea. Amenorrhea is a potential side effect from using low-dose or extended oral CHCs and depot medroxyprogesterone acetate. Many women experience delayed return of menses after CHC discontinuation. If spontaneous resolution of amenorrhea does not occur within 3 to 6 months following CHC discontinuation, evaluation for other conditions should be considered (eg, PCOS).

---

### Patient Encounter 1, Part 2

Additional workup reveals:
- **PMH:** asthma
- **PSH:** none
- **FH:** Mother and father are alive and well. She has two younger siblings (ages 17 and 12) who are alive and well.
- **SH:** (+) smoking; (−) drug use; (+) alcohol use (2–4 drinks per week)
- **Meds:** Fluticasone 110 mcg 2 puffs twice daily and albuterol 90 mcg 2 puffs pm SOB
- **Past Gynecologic Hx:** Menarche at age 11; never pregnant; (+) sexual activity; 6 sexual partners; (+) history of Chlamydia; (+) history of painful menses beginning at age 12; (+) heavy menstrual flow; menstrual cycle 26 to 28 days.
- **ROS:** (−) fatigue; (−) headaches; (+) mild acne on face and chest; (+) moderate to severe pelvic pain with menses
- **HEENT:** (−) hirsutism
- **Breasts:** (−) galactorrhea
- **Pelvic examination:** normal appearance of external genitalia and vagina, cervix without lesions, uterus midposition without masses, adnexa without masses
- **Labs:** (−) hCG

**Given this information, what is your assessment of this patient’s condition?**

FIGURE 49–2. Summary of normal menstrual cycle. (FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.)

Clinical Presentation and Diagnosis of Amenorrhea

General
- Concerns about cessation of menses and fertility implications
- Not generally in acute distress

Symptoms
- Cessation of menses
- Possible reports of infertility, vaginal dryness, decreased libido

Signs
- Absence of menses by age 15 in the presence of normal secondary sexual development or within 5 years of menarche (if occurs before age 10).
- Recent significant weight loss or gain
- Presence of acne, hirsutism, hair loss, or acanthosis nigricans may suggest androgen excess.

Laboratory Tests
- Pregnancy test
- TSH
- Prolactin
- If PCOS is suspected, consider free or total testosterone, 17-hydroxyprogesterone, fasting glucose, and fasting lipid panel.
- If premature ovarian failure is suspected, consider follicle-stimulating hormone (FSH) and luteinizing hormone (LH) measurements.

Other Diagnostic Tests
- Progesterone challenge
- Pelvic ultrasound to evaluate for polycystic ovaries

Treatment

 Desired Outcomes
- Treatment goals include restoring the normal menstrual cycle, preserving bone density, preventing bone loss, improving quality of life, and restoring ovulation, thus improving fertility.

Amenorrhea attributable to hypoestrogenism (eg, premature ovarian insufficiency) can cause hot flashes and dyspareunia. In prepubertal females, the absence of secondary sexual characteristics and menarche may occur.

 Nonpharmacologic Therapy
Nonpharmacologic therapy for amenorrhea depends on the underlying cause. Amenorrhea secondary to undernutrition or anorexia may respond to weight gain and psychotherapy. If excessive exercise is the culprit, exercise reduction is recommended.

 Pharmacologic Therapy

Estrogen/Progestin Replacement Therapy
For most conditions associated with primary or secondary amenorrhea, estrogen treatment is recommended. To minimize risk of endometrial hyperplasia and cancer, progestin should also be given to women with an intact uterus. Estrogen’s role is to reduce osteoporosis risk, stimulate and maintain secondary sexual characteristics, and improve quality of life. Table 49–1 lists the types and doses of estrogen and progestin therapy for amenorrhea.

Dopamine Agonists
In women with hyperprolactinemia who desire conception, dopamine agonists are an option. Dopamine agonists reduce prolactin levels and resolve amenorrhea. Additionally, they restore ovulation in 80% to 90% of women. The most commonly studied agents are bromocriptine and cabergoline.

Progestins
Progestins have long been used to induce withdrawal bleeding in women with secondary amenorrhea. Efficacy varies depending on the formulation used. Withdrawal bleeding occurs with intramuscularly injected progesterone and oral medroxyprogesterone acetate in 70% and 95% of patients, respectively. The usual dose of medroxyprogesterone acetate is 10 mg orally once daily for 7 to 10 days.

Insulin-Sensitizing Agents
Amenorrhea related to anovulation and PCOS may respond to insulin sensitizing agents. Using metformin for this purpose is discussed in the anovulatory bleeding section.

All patients experiencing amenorrhea should follow a diet rich in calcium and vitamin D to support bone health. Supplemental calcium and vitamin D (1200 mg/800 International Units per day) should be recommended for patients with inadequate dietary consumption. Figure 49–4 illustrates treatment recommendations for amenorrhea.

Amenorrhea in Adolescents
Adolescence is when peak bone mass is achieved. The cause of amenorrhea and appropriate treatment must be identified promptly in this population because hypoestrogenism contributes negatively to bone development. Estrogen replacement, typically via a CHC, is important. Although recent data suggest that CHCs and depot medroxyprogesterone acetate may reduce bone mineral density (BMD) for short term, their long-term effects on fractures are unknown. These negative BMD effects
appear to be reversible; therefore, CHCs are recommended in the adolescent population. Ensuring adequate dietary or supplemental calcium and vitamin D intake in this population is imperative.

ANOVULATORY BLEEDING

Anovulatory uterine bleeding (AUB) is irregular menstrual bleeding from the endometrium ranging from light spotting to heavy blood flow. It includes noncyclic menstrual bleeding due to ovulatory dysfunction (AUB-O), including anovulation or oligo-ovulation. AUB-O is secondary to the effects of unopposed estrogen and does not include bleeding owing to an anatomic lesion of the uterus. AUB is a diagnosis of exclusion and includes PCOS, which typically presents with irregular menstrual bleeding, hirsutism, obesity, and/or infertility.

Epidemiology and Etiology

Anovulatory uterine bleeding is the most common form of noncyclic uterine bleeding. Medical care is often pursued to regulate menstrual cycles or improve fertility. All women of reproductive age should have a pregnancy test when presenting with irregular menstrual bleeding. Anovulation results from dysfunction at any level of the hypothalamic-pituitary-ovarian (HPO) axis which can be due to physiologic life stages such as adolescence, perimenopause, pregnancy, and lactation or pathologic causes (see Table 49–2).

During adolescence, ovulatory menstrual cycles may not be regular for 12 to 18 months after menarche. Ovulation frequency is related to the age at and time since menarche. In the year following menarche, the feedback mechanism in the HPO axis may be immature, and the luteinizing hormone (LH) surge needed for ovulation fails to occur. During perimenopause, anovulatory cycles occur due to declining quality and quantity of ovarian follicles. As ovarian function declines, estrogen secretion continues, and progesterone secretion decreases. Chronic anovulatory cycles and unopposed estrogen secretion lead to endometrial proliferation and increased risk of polyps, endometrial hyperplasia, and endometrial carcinoma.

Anovulation also occurs at any time during the reproductive years due to a pathologic cause. The most common causes of nonphysiologic ovulatory dysfunction are PCOS, hypothalamic amenorrhea, hyperprolactinemia, and premature ovarian failure. PCOS, responsible for 55% to 91% of ovulatory dysfunction cases, occurs in approximately 7% of women.

Pathophysiology

A normal ovulatory cycle includes follicular development, ovulation, corpus luteum development, and luteolysis. During the cycle, the endometrium proliferates and undergoes secretory changes and desquamation. This is influenced by estrogen alone, then by estrogen and progesterone, and culminates with estrogen and progesterone withdrawal. Progesterone stops endometrial growth and stimulates endometrial differentiation. In anovulatory women, a corpus luteum is not formed, and the ovary does not secrete progesterone. Without progesterone, there is no endometrial desquamation or differentiation. Chronic unopposed estrogen causes endometrial proliferation. The endometrium becomes vascular and fragile, resulting in noncyclic menstrual bleeding. The endometrium may also become hyperplastic and progress to a precancerous state, increasing the woman’s risk of endometrial cancer (see Table 49–2).

The most common pathologic cause of anovulation is PCOS. Two sets of closely related criteria have been developed. The Rotterdam criteria identify PCOS as a syndrome of ovarian dysfunction diagnosed when two of the following characteristics exist: (a) oligoanovulation or anovulation; (b) clinical signs (hirsutism, acne) or laboratory evidence of hyperandrogenism (total testosterone and sex hormone-binding globulin); and (c) polycystic ovary morphology on ultrasound.

The Androgen Excess and PCOS Society (AE-PCOS) defines PCOS as hyperandrogenism (clinical or biochemical), ovarian dysfunction...

(oigoanovulation or polycystic ovaries) and the exclusion of other causes of androgen excess. No gene or environmental substance appears to cause PCOS. However, familial clustering of PCOS cases suggests that genetics play a role. Insulin resistance, hyperandrogenism, and changes in gonadotropins also influence PCOS development. The underlying cause for increased androgens is unknown.

Recently, discussion regarding the link to cardiovascular disease has been emphasized. PCOS is associated with two to five times increased risk of developing type 2 diabetes. In women with PCOS, approximately 60% to 80% have impaired glucose tolerance (IGT). Additionally, in obese women with PCOS, IGT prevalence increases to 95%, and 70% have dyslipidemia. Women with PCOS should be screened for IGT, diabetes, hypertension, and dyslipidemia. If any present, there is an increased risk of cardiovascular events.

### Treatment

**Desired Outcomes**

The desired outcomes of therapy are to stop acute bleeding, prevent future episodes of noncyclic bleeding, decrease long-term complications of ovulation (eg, osteopenia and infertility), and improve overall quality of life.

**Nonpharmacologic Therapy**

Nonpharmacologic treatment options depend on the underlying cause. For all women with PCOS, weight loss may be beneficial. In overweight or obese women, a 5% reduction in weight has been associated with resumption of menses, improved pregnancy rates, and decreased hirsutism, glucose, and lipid levels. In women who have completed childbearing or who have failed medical management, endometrial ablation or resection, and
SECTION 8 | GYNECOLOGIC AND OBSTETRIC DISORDERS

Hysterectomy are surgical options. The preferred procedure is unclear. For short term, it appears that ablation or resection results in less morbidity and shorter recovery periods. However, a significant number of these women eventually undergo hysterectomy within 5 years.

Pharmacologic Therapy
Table 49–1 summarizes therapeutic agents and doses.

**Estrogen** Estrogen is the recommended treatment for managing acute bleeding episodes. It promotes endometrial growth and stabilization.

It should then be continued to prevent recurrent anovulatory bleeding. Long-term therapy with a CHC reduces the risk of endometrial cancer compared to unopposed estrogen therapy.

CHCs suppress ovarian hormones and adrenal androgen production and indirectly increase sex hormone–binding globulin (SHBG). This, in turn, binds and reduces circulating androgen.

For women with high androgen levels and related signs (eg, hirsutism, acne), low-dose CHCs (35 mcg or less ethinyl estradiol) are the treatment of choice.

A CHC containing drospirenone, which has a greater impact on increasing SHBG and antiandrogenic effects, could be considered.

However, to date there is no consensus regarding the best CHC choice for treating PCOS.

**Medroxyprogesterone Acetate Depot** and intermittent oral medroxyprogesterone acetate suppresses pituitary gonadotropins and circulating androgens in women with PCOS.

Furthermore, cyclic progesterone may benefit women older than 40 years with anovulatory bleeding. Similar to the use of CHCs, oral medroxyprogesterone acetate has averted emergency surgeries in 100% of patients with acute uterine bleeding justifying immediate medical attention.

**Estrogen Modulators** If the goal is to induce ovulation, the treatment of choice is clomiphene citrate. It is approximately
Acute distress may or may not be present.

Reports of heavy/prolonged menstrual flow.

Pelvic magnetic resonance imaging (MRI)

Orthostasis, tachycardia, and pallor may be noted,

Sonohysterogram

Pelvic ultrasound

Endometrial biopsy

Complete blood count (CBC) and ferritin levels;

Dysmenorrhea may be an accompanying symptom

Fatigue and light-headedness in the case of severe blood

If the history dictates, testing may be done to identify

Hysteroscopy

Pap smear

Insulin-sensitizing Agents Metformin improves insulin sensitivity and is recommended in women who cannot tolerate CHC and have IGT or type-2 diabetes mellitus.13,33,38

In patients with PCOS, it is associated with reduced circulating androgen concentrations, increased ovulation rates, and improved glucose tolerance. Additionally, metformin may decrease cardiovascular risk and promote weight loss.13 These improvements are attributed to the SHBG increase that occurs via increased insulin sensitivity. Notably, metformin, a pregnancy category B agent, is not recommended as monotherapy to improve ovulation and fertility. Thiazolidinediones are no longer recommended due to a poor risk-benefit ratio.33

Anovulatory Bleeding in Adolescents

Anovulatory cycles are common in the perimenarchial years. Ovulation typically is established a year or more following menarche. When anovulatory bleeding occurs in this population, it may be excessive. Thus, the patient should be evaluated for blood dyscrasias, including von Willebrand disease, prothrombin deficiency, and idiopathic thrombocytopenia purpura.24,25

In adolescents, blood dyscrasias should be treated. Acute, severe bleeding is managed with high-dose estrogen. Low-dose CHCs (35 mcg or less ethinyl estradiol) are the treatment of choice in adolescents with chronic anovulation.24 If obesity is present, lifestyle changes are also recommended first line, and if IGT or metabolic syndrome is present, metformin can be recommended.33

MENORRHAGIA

Menorrhagia describes prolonged menstrual bleeding (lasting greater than 7 days) or cyclic, heavy menstrual bleeding (HMB; greater than 80 mL per cycle).23,30,39 It is difficult to quantify menstrual blood loss in clinical practice. Many women with less than 80 mL of blood loss seek medical attention with concerns of containment flow problems, unpredictable heavy flow, reduced quality of life, and other dysmenorrhea symptoms.39

Epidemiology and Etiology

Menorrhagia rates in healthy women range from 9% to 14%, but can be as high as 30%.23,30

Clinical Presentation and Diagnosis of Menorrhagia

General
• Acute distress may or may not be present

Symptoms
• Reports of heavy/prolonged menstrual flow.
• Fatigue and light-headedness in the case of severe blood loss.
• Dysmenorrhea may be an accompanying symptom

Signs
• Orthostasis, tachycardia, and pallor may be noted, especially with significant acute blood loss.

Laboratory Tests
• Complete blood count (CBC) and ferritin levels; hemoglobin and hematocrit results may be low.
• If the history dictates, testing may be done to identify coagulation disorder(s) as a cause.

Other Diagnostic Tests
• Pelvic ultrasound
• Pelvic magnetic resonance imaging (MRI)
• Pap smear
• Endometrial biopsy
• Hysteroscopy
• Sonohysterogram
Intrauterine pregnancy, ectopic pregnancy, and miscarriage are at the top of the differential diagnosis list for any woman presenting with heavy menses. Additionally, genital tract malignancies and infections may present with abnormal bleeding.

Systemic disorders include coagulation dysfunction such as von Willebrand disease and platelet function disorders. Hypothyroidism is also associated with heavy menses. Specific reproductive tract causes of menorrhagia are more common in older childbearing women, and they include fibroids, adenomyosis, endometrial polyps, and gynecologic malignancies.

Pathophysiology

Table 49–2 describes the pathophysiology of menorrhagia and specific conditions resulting in menorrhagia.

Treatment

**Desired Outcomes**

Goals of therapy are to reduce menstrual blood flow, reduce risk of anemia, improve quality of life, and defer the need for surgical intervention. Treatment recommendations are outlined in Table 49–1 and Figure 49–5.

**Nonpharmacologic Therapy**

Surgical interventions are reserved for patients nonresponsive to pharmacologic treatment and include endometrial ablation and hysterectomy.

**Pharmacologic Therapy**

**Nonsteroidal Anti-inflammatory Drugs (NSAIDs)**

NSAIDs are first-line treatments for menorrhagia associated with ovulatory cycles. They are taken only during menses, and a 20% to 35% reduction in blood loss is reported in 75% of treated women.

Patient Encounter 3

A 14-year-old girl presents to her physician reporting moderate pelvic pain and cramping during menses. She also notes that her menses are “heavy” and require a change in tampon every 3–4 hours. Her last menstrual cycle was 12 days ago, and she had her first menstrual cycle at age 12. She is not sexually active. She does not take any routine medications. She is on the high school volleyball team.

Identify the treatment goals for this patient’s menorrhagia.

What diagnostic tests should be considered?

What pharmacologic therapies are recommended for this patient?

What monitoring parameters are recommended to assess efficacy and safety of the therapeutic options?
Table 49–3

Expected Outcome Measures for Selected Menstrual Bleeding Disorders

<table>
<thead>
<tr>
<th>Menstrual Disorder</th>
<th>Expected Outcome Measures</th>
</tr>
</thead>
</table>
| Amenorrhea          | Efficacy: Normal breast development (especially primary amenorrhea in adolescents); BMD preservation/improvement; return of menses.  
  Time to relief/effect: Menses should occur within 1–2 months of therapy. |
| Anovulatory bleeding| Efficacy: Alleviation of acute bleeding when present; ovulation and subsequent pregnancy in women desiring this; reduced risk of developing the long-term complications of PCOS (eg, diabetes and cardiovascular disease); improved quality of life.  
  Time to relief/effect: The acute treatment of heavy bleeding should reduce bleeding within 10 days of therapy onset; return of ovulation may require several months of therapy; when oral CHCs are used, abnormal bleeding control can be expected within 1–2 treatment cycles. |
| Dysmenorrhea        | Efficacy: Reduction in menstes-related pelvic pain; reduction in time lost from work/school; improved quality of life.  
  Time to relief/effect: Improvement in pain may be observed within hours of NSAID therapy; improvement with other options such as oral CHCs may be observed after a full 1–3 cycles of use. |
| Menorrhagia         | Efficacy: Decline in amount of blood loss with menses (monitor a decline in the number of times feminine hygiene products such as pads and tampons require changing during menses); increase in hemoglobin/hematocrit if anemia was present as because of menorrhagia.  
  Time to relief/effect: A decline in menstrual blood loss should be realized within 1–2 cycles of therapy initiation. |

BMD, bone mineral density; CHCs, combination hormonal contraceptives; NSAID, nonsteroidal anti-inflammatory drug; PCOS, polycystic ovary syndrome.

the amount of pretreatment blood loss. They may also improve dysmenorrhea.

**Combination Hormonal Contraceptives** CHCs are beneficial to women with menorrhagia who do not desire pregnancy. A 40% to 50% reduction in menstrual blood loss is reported in 68% of menorrhagia patients treated with oral CHCs containing greater than or equal to 35 mcg estradiol. Continuous and extended cycle options may also reduce the number of menstrual cycles. As with NSAIDs, the reduction in blood loss is proportional to pretreatment blood loss.

**Progestins** Menorrhagia may also be treated with the levonorgestrel-releasing IUD, which consistently reduces menstrual flow by 75% to 95%, and after 12 months, 20% to 80% of women experience amenorrhea. When compared with endometrial ablation, the levonorgestrel IUD causes similar reductions in menstrual blood loss after 6, 12, and 24 months.

**Patient Care Process**

**Patient Assessment:**
- Based on physical examination, history, and review of systems, additional work-up may be necessary (eg, amenorrhea, menorrhagia, AUB, or PMDD).
- Document symptoms.
- Conduct a medication history. Have any treatments helped in the past?
- Review the medical history and laboratory data. Does the patient have any complications, such as symptoms of anemia in patients presenting with menorrhagia or difficulty conceiving in women with amenorrhea or anovulatory bleeding?
- Review available diagnostic data to determine hormonal, reproductive, and pregnancy status. Does the patient need a pregnancy test?

**Therapy Evaluation:**
- Is current pharmacotherapy safe and effective; is dosing appropriate?
- Is the patient adherent to current therapy?
- Does the patient have prescription insurance coverage?

**Care Plan Development:**
- Educate the patient on lifestyle modifications that will improve symptoms and prevent complications.
- Select pharmacotherapy, if indicated, that is safe and effective.
- Determine whether long-term maintenance treatment is necessary.
- Address any patient concerns on quality of life (physical, psychological, and social functioning) and infertility.
- Discuss the importance of adherence to medication management and lifestyle modifications.

**Follow-up Evaluation:**
- Develop a plan to assess effectiveness and safety of pharmacotherapy.
- Assess improvement in quality-of-life and well-being.
- Review medical history, physical examination findings, laboratory and diagnostic tests.
- Evaluate for adverse drug reactions, drug allergies, and drug interactions.
Compared with hysterectomy, it leads to similar rates of satisfaction and improved quality of life.\textsuperscript{10,42}

Cyclic progestin therapy, either during the luteal phase or for 21 days of the menstrual cycle, reduces menstrual blood loss.\textsuperscript{10} The levonorgestrel IUD is more effective than oral norethindrone administered cyclically.\textsuperscript{16} In a small open-label study, the levonorgestrel IUD resulted in a greater menstrual blood loss reduction and number of lost days at work or school compared with oral CHCs.\textsuperscript{43} Oral progestin therapy is considered a third-line option.\textsuperscript{10}

**Tranexamic Acid** Tranexamic acid reduces plasmin activity and tissue plasminogen activator.\textsuperscript{10,44} While an immediate-release product has been available for a long time, a modified-release product has recently become available. It has better gastrointestinal tolerability and gives women another non-hormonal option to manage menorrhagia.\textsuperscript{44,45} Additionally, it can be recommended for women with von Willebrand disease.

**Menorrhagia in Adolescents**

Up to 50% of adolescents with menorrhagia have been shown to have a bleeding disorder, most commonly von Willebrand disease or platelet dysfunction.\textsuperscript{23} Although von Willebrand disease has a 1% to 2% incidence in the general population, it is estimated that 5% to 36% of adolescents presenting with heavy menses have this disorder.\textsuperscript{23,24} Platelet function disorders exist in 2% to 44% of adolescents with menorrhagia.\textsuperscript{23}

**OUTCOME EVALUATION**

Treatment success for menstruation-related disorders is measured by the degree to which treatment (a) relieves or reverses symptoms, (b) prevents or reverses complications (eg, osteoporosis, anemia, and infertility), and (c) causes minimal adverse effects. Resumption of regular menstrual cycles with minimal premenstrual or dysmenorrhea symptoms should occur. Depending on the desire for conception and related therapy, these cycles may be ovulatory or anovulatory.

Assess treatment effectiveness in reinstating normal menstrual cycles with minimal adverse effects after an appropriate treatment interval (1–2 months). Assess improvement in well-being and quality-of-life (eg, physical, psychological, and social functioning). Evaluate the patient for adverse drug reactions (see Table 49–1), drug allergies, and drug interactions. Table 49–3 lists the expected outcome measures for each discussed menstruation-related disorder.

**LEARNING OBJECTIVES**

Upon completion of the chapter, the reader will be able to:

1. Explain the physiologic changes associated with menopause.
2. Identify the signs and symptoms associated with menopause.
3. Determine the desired therapeutic outcomes for a patient taking hormone therapy (HT).
4. Explain how to evaluate a patient for the appropriate use of HT.
5. Recommend nonpharmacologic therapy for menopausal symptoms.
6. List the adverse effects of and contraindications to HT.
7. Differentiate between topical and systemic forms of HT.
8. Explain the risks and benefits associated with HT.
9. Educate a patient regarding the proper use and potential adverse effects of HT.
10. Describe the monitoring parameters for a patient taking HT.
11. Describe the circumstances under which nonhormonal therapies for menopausal symptoms should be considered.

**INTRODUCTION**

Menopause is the permanent cessation of menses following the loss of ovarian follicular activity. The diagnosis of menopause is primarily a clinical one and is made after a woman experiences amenorrhea for 12 consecutive months. The loss of ovarian follicular activity leads to an increase in follicle-stimulating hormone (FSH), which, on laboratory examination, may help to confirm the diagnosis.

The role of hormone therapy (HT) has changed dramatically over the years. HT has long been prescribed for relief of menopausal symptoms and, until recent years, has been purported to protect women from coronary heart disease (CHD). The reason behind recommending HT in postmenopausal women revolved around a simple theory: If the hormones lost during menopause were replaced through drug therapy, women would be protected from both menopausal symptoms and chronic diseases that often follow after a woman experiences menopause. Recent studies have disproved this theory.

In 1996, the United States Preventive Services Task Force first published its recommendations that not all postmenopausal women should be prescribed HT, but that therapy should be individualized based on risk factors. This recommendation was further supported with publication of the Heart and Estrogen/Progestin Replacement Study (HERS) in 1998, which demonstrated that women who had established CHD were at an increased risk of experiencing a myocardial infarction within the first year of HT use compared with a similar group of women without CHD risk factors. As a result, the authors concluded that HT should not be recommended for the secondary prevention of CHD. Then, in 2002, the Women’s Health Initiative (WHI) study was published. This trial demonstrated that HT was not protective against CHD but rather could increase the risk in women with underlying CHD risk factors. The risk of breast cancer was also increased after a woman was on combination estrogen and progestogen for approximately 3 years. It should be noted that this was not the case with estrogen alone. As a result of this study, the US Food and Drug Administration (FDA) issued a statement that HT, in general, should not be initiated or continued for the primary prevention of CHD.

This series of trials led to dramatic changes in how HT is prescribed and greater understanding of the associated risks. HT, once thought of as a cure-all for menopausal symptoms, is now a therapy that should be used primarily to reduce the frequency and severity of moderate to severe vasomotor symptoms associated with menopause in women without risk factors for CHD or breast cancer. The changes that have occurred over the years in the use of HT further support the importance of evidence-based practice and judicious medication use.

**EPIDEMIOLOGY AND ETIOLOGY**

Menopause is a period of time marked by loss of ovarian follicular activity, inadequate estradiol production, and the subsequent cessation of menses. The median age for a woman to experience menopause is 52 years. However, women who have undergone a total abdominal hysterectomy with bilateral salpingo-oophorectomy (surgical menopause) generally experience menopause earlier.
compared with women who experience natural menopause. Some other factors that may be associated with early menopause include low body weight, increased menstrual cycle length, nul-
liparity, and smoking. Smokers generally experience menopause approximately 2 years earlier than nonsmokers.¹

The usual transitional period prior to menopause, known as perimenopause or the climacteric, is a period when hormonal and biologic changes begin to occur. These changes may begin 2 to 8 years prior to menopause and eventually lead to irregular menstrual cycles, an increase in cycle interval, and a decrease in cycle length. During this time, women also may experience physical symptoms similar to menopausal symptoms, which may require treatment depending on symptom severity.²

Because the perimenopausal and postmenopausal periods are marked by many biologic and endocrinologic changes, women should inform their health care provider when they experience any signs and symptoms in order to discuss the most appropriate therapeutic approach.

PHYSIOLOGY

Reproductive physiology is regulated primarily by the hypothalamic–pituitary–ovarian axis. The hypothalamus secretes gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary to secrete FSH and luteinizing hormone (LH). FSH and LH regulate ovarian function and stimulate the ovary to produce sex steroids. All these hormones are influenced by a negative-feedback system and will increase or decrease based on the levels of estradiol and progesterone.

The physiologic changes that occur during the perimenopausal and menopausal periods are caused by the decrease and eventual loss of ovarian follicular activity. As women age, the number of ovarian follicles decreases, and the remaining follicles require higher levels of FSH for maturation and ovulation. During perimenopause, anovulatory cycles are more likely, and the lack of progesterone production leads to irregular and unpredictable menses. During menopause, FSH concentrations increase 10- to 15-fold, LH concentrations increase fivefold, and levels of circulating estradiol decrease by more than 90%.³

KEY CONCEPT

Common symptoms of menopause include vasomotor symptoms (hot flashes, night sweats), vulvovaginal atrophy, vaginal dryness, and dyspareunia. Women less commonly may experience mood swings, depression, insomnia, arthralgia, myalgia, urinary frequency, and decreased libido. Menopausal symptoms tend to be more severe in women who undergo surgical menopause compared with natural menopause because of the more rapid decline in estrogen concentrations.³ Women who seek medical treatment should undergo laboratory evaluation to rule out other conditions that may present with similar symptoms, such as abnormal thyroid function or pituitary adenoma. Once symptoms have been evaluated and other conditions have been excluded, HT may be considered.

TREATMENT

Desired Outcomes

KEY CONCEPT

HT remains the most effective treatment for vasomotor symptoms and vulvovaginal atrophy and can be considered, especially for women experiencing moderate to severe symptoms. The goals of treatment are to alleviate or reduce menopausal symptoms and to improve the patient’s quality of life (QOL) while minimizing adverse effects of therapy. The appropriate route of administration should be chosen based on individual patient symptoms, and therapy should be continued at the lowest dose for the shortest duration consistent with treatment goals for each patient.

General Approach to Treatment

There are a number of national and international guidelines and consensus statements available on the management of menopause.⁴⁻⁹ The most current guidelines should always be consulted before making pharmacotherapeutic recommendations for women. Women suffering from vasomotor symptoms
should attempt lifestyle or behavioral modifications before seeking medical treatment. Women who seek medical treatment usually suffer from symptoms that diminish their QOL, such as multiple hot flashes per day or week, sleep disturbances, vaginal dryness, or mood swings. HT should be considered for these women but is not the most appropriate choice for all women.

**KEY CONCEPT.** Women should receive a thorough history and physical examination, including assessing for CHD and breast cancer risk factors and contraindications, before HT is considered. They should be informed of the risks and the benefits of HT and encouraged to be involved in the decision-making process. If a woman does not have any contraindications to HT, including CHD or significant CHD risk factors, and also does not have a personal history of breast cancer, HT could be an appropriate therapy option (Figure 50–1). Women who have undergone a hysterectomy need only be prescribed estrogen. A progestogen should be added to the estrogen only for women with an intact uterus. Alternative and nonhormonal treatment options are available for women who are not candidates for HT, but they have limited effectiveness and may also have adverse effects.

**Nonpharmacologic Therapy**

Nonpharmacologic therapies for menopause-related symptoms have not been studied in large randomized trials, and evidence of benefit is not well documented. Due to the minimal adverse effects of these interventions, patients should try lifestyle or behavioral modifications before and in addition to pharmacologic therapy. The most common nonpharmacologic interventions for vasomotor symptoms include the following:

- Smoking cessation
- Limit alcohol and caffeine
- Limit hot beverages (eg, coffee/tea, soups)
- Limit spicy foods
- Keep cool, and dress in layers
- Stress reduction (eg, meditation, relaxation exercises)
- Increase exercise
- Paced respiration

Exercise demonstrated an improvement in QOL but did not improve vasomotor symptoms. Paced respiration, a form of deep, slow breathing, improved vasomotor symptoms in a small group of patients.

Dyspareunia may result from vaginal dryness. Water-based lubricants may provide relief for several hours after application. Moisturizers may provide relief for a longer period of time and potentially can prevent infections by maintaining the acidic environment in the vagina. Both these treatments require frequent application.

A decline in estrogen concentrations also may be associated with urinary stress incontinence. *Kegel exercises* are recommended as a first-line intervention for stress incontinence, although pharmacologic therapy also may be necessary. Kegel exercises strengthen the pelvic floor muscles and help to keep the urethral sphincter from relaxing at inappropriate times, such as when lifting heavy objects, coughing, or sneezing. These exercises have no adverse effects, take little time, may be done inconspicuously, and when done correctly, may help to restore normal urine flow.

---

**Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests**

The workup reveals the following additional information:

**PMH:** Hypertension since age 45, currently controlled; hyperlipidemia, currently controlled; hypothyroidism since age 25, but symptoms indicative of worsening control; hysterectomy in 2010.

**FH:** Father: Alive with HTN and CHD (MI at age 60). Mother: Alive with hypothyroidism, HTN, and GERD. Siblings: Two sisters alive and well, menopausal with hx of hot flashes.

**SH:** Occupation: Nurse; nonsmoker; drinks one to two glasses of red wine with dinner on the weekends; denies illicit drug use.

**Meds:** Lisinopril/HCTZ 20/12.5 mg once daily; simvastatin 40 mg at bedtime; Synthroid 0.075 mg by mouth once daily; multivitamin by mouth once daily.

**ROS:** (+) hot flashes, night sweats, vaginal dryness and itching; (+) insomnia, bowel changes, 5-lb weight loss since last visit 6 months ago.

**PE:**

**VS:** BP 128/78, P 92, RR 16, T 37.0°C (98.6°F), Wt 74.5 kg (164 lb)

**HEENT:** WNL

**Neck:** Supple; no bruits, no adenopathy, no thyromegaly.

**Breasts:** Supple; no masses

**CV:** RRR, normal S1 and S2; no murmurs, rubs, or gallops

**Abd:** Soft, nontender, nondistended; (+) BS, no masses

**Genitourinary:** Pelvic examination normal except (+) mucosal atrophy; (+) hysterectomy

**Labs:**

**FSH:** 76 mIU/mL (76 IU/L)

**TSH:** 0.3 μIU/mL (0.3 mIU/L)

**Chem-7:** Na 135 mEq/L (135 mmol/L), K 4.5 mEq/L (4.5 mmol/L), Cl 109 mEq/L (109 mmol/L), CO2 25 mEq/L (25 mmol/L), BUN 9 mg/dL (3.2 mmol/L), SCR 0.9 mg/dL (80 μmol/L), Glucose 98 mg/dL (5.4 mmol/L)

**CBC:** Hgb 13 g/dL (130 g/L or 8.06 mmol/L), Hct 39% (0.39 volume fraction), WBC 5.5 × 109/mm3 (5.5 × 109/L), platelets 234 × 109/mm3 (234 × 109/L)

**Fasting lipid levels:** TC 200 mg/dL (5.17 mmol/L), low-density lipoprotein (LDL) 126 mg/dL (3.26 mmol/L), high-density lipoprotein (HDL) 50 mg/dL (1.30 mmol/L), Triglycerides (TG) 115 mg/dL (1.30 mmol/L)

Pharmacologic Therapy

**Estrogens**

Estrogen is indicated for the treatment of moderate to severe vasomotor symptoms and vulvovaginal atrophy associated with menopause. In addition, it is indicated for the prevention of postmenopausal osteoporosis in women with significant risk; however, it is recommended that nonestrogen medications be used long-term. **KEY CONCEPT** Oral or transdermal estrogen products should be prescribed at the lowest effective dose and for the shortest duration possible to provide relief of vasomotor symptoms. Topical vaginal products in the form of creams, tablets, or rings should be prescribed for women exclusively experiencing vulvovaginal atrophy.

Many systemically administered estrogen products are available in the United States. Transdermal estrogen preparations are also available and usually are prescribed for patients who experience adverse effects, elevated triglycerides (TG), or liver function abnormalities while taking an oral product. Although there have been no randomized controlled trials (RCTs) published, one case control study suggests that transdermal preparations have a lower incidence of venous thromboembolism (VTE) than oral preparations.3,14

**KEY CONCEPT** Women who have an intact uterus should be prescribed a progestogen in addition to estrogen in order to decrease the risk of endometrial hyperplasia and endometrial cancer.1 Progestogens should be prescribed for at least 12 to 14 days of the month and often are prescribed continuously. Even low doses of oral estrogen therapy, as well as high dose vaginal preparations, require daily or intermittent administration of a progestogen in order to provide endometrial protection. **Table 50–1** lists estrogen and progestogen preparations and dosages.

**Adverse Effects**

Therapy with estrogen with or without a progestogen should be initiated at the lowest dose in order to minimize adverse effects. Because the adverse effects of these preparations can be similar, it may be difficult to assess whether the estrogen or the progestogen is the cause. Changing preparations, particularly the progestogen, or changing the method of administration may help to alleviate adverse effects. **Table 50–2** lists the adverse effects that may be associated with estrogen and progestogen preparations.

**Contraindications**

- HT should not be prescribed to women with a history of or active thromboembolic disease, breast cancer or estrogen-dependent neoplasm, pregnancy, liver disease, or undiagnosed vaginal bleeding. It also should not be used for the prevention or treatment of cardiovascular disease, cerebrovascular disease, or dementia.3

**Methods of Administration**

Cyclic Estrogen and Progestogen Estrogen is administered daily, and progestogen is administered for 12 to 14 days of the month. The disadvantage of this method of administration is the return of monthly menses in approximately 90% of women 1 to 2 days following the last progestogen dose. Women may view this scheduled bleeding as an advantage to this method of administration as it limits spotting or soiling of undergarments.

Continuous Combined Estrogen and Progestogen Estrogen and progestogen are administered daily and result in endometrial atrophy. Therefore, women do not experience a withdrawal bleed but may experience unanticipated breakthrough bleeding or spotting during the month. Although this may sound more appealing than a withdrawal bleed, women may view the unpredictable bleeding or spotting as a disadvantage to this type of administration. If bleeding persists beyond 6 to 12 months, women should seek medical attention to rule out endometrial hypertrophy or carcinoma.

**Low-Dose HT**

There is an increasing body of evidence proving the effectiveness of low-dose HT regimens in the management of menopausal symptoms. Several trials demonstrated that lower doses of conjugated equine estrogen (CEE) ± medroxyprogesterone acetate (MPA) (CEE 0.45 mg or 0.3 mg ± MPA 2.5 mg or 1.5 mg) decreased hot flashes comparable with standard HT, improved vulvovaginal atrophy, increased bone mineral density (BMD) at the spine and hip, and provided sufficient endometrial protection.17–20 Currently, no data are available on the effects of low-dose HT on the incidence of VTE, breast cancer, or CHD. Although many women have switched to low-dose HT, time will tell if lower doses translate into lower risks.

**Bioidentical HT**

Bioidentical hormones are exogenous hormones that are identical to those produced in a woman’s body (eg, estradiol, estrone, estriol, and progesterone). They are either commercially manufactured or chemically compounded in pharmacies into formulations such as topical creams, gels, and suppositories. The commercially manufactured prescription products are subject to regulation by the FDA and have been tested for potency, purity, efficacy, and safety (see **Table 50–1**). Conversely, pharmacist-compounded formulations are not subject to the same regulations and therefore, the efficacy and safety may be questionable. Often women view bioidentical hormones, particularly the pharmacist-compounded formulations, as “natural” and assume these formulations are safer than currently marketed prescription hormone products. Women may feel more comfortable using compounded products that are formulated based on individual hormone levels; however, due to a lack of regulation, these products may potentially cause more harm than benefit. In addition, pharmacist-compounded formulations can result in higher costs, because they are generally not covered by third-party payers. There is little evidence comparing the safety and efficacy of conventional HT to prescription bioidentical HT, and thus the same risks and benefits should be assumed.3,21

**Benefits of HT**

**Vasomotor Symptoms** HT remains the most effective treatment for vasomotor symptoms, and systemic HT should be considered only in women experiencing these symptoms. Benefits must outweigh risks, and decisions should be made only after careful consideration by the woman and her health care provider. If it is decided to use HT, it should be prescribed at the lowest dose that relieves or reduces menopausal symptoms and should be recommended only for short-term use (generally less than 5 years). Women should be reassessed every 6 to 12 months, and discontinuation of therapy should be considered.

**Vulvovaginal Atrophy** Approximately 50% of postmenopausal women experience vulvovaginal atrophy and seek medical attention. Vulvovaginal atrophy is associated with vaginal dryness and dyspareunia and also may be associated with recurrent urinary tract infections, urethritis, and urinary urgency and frequency.
Topical vaginal preparations generally should be prescribed as first-line therapy unless the patient is also experiencing vasomotor symptoms. Local vaginal estrogen has demonstrated increased efficacy over systemic estrogen and generally does not require supplementation with a progestogen in women with an intact uterus using low or ultralow doses. Women using regular or high doses of topical estrogen products may require intermittent treatment with a progestogen. Although few data are available on the appropriate progestogen dose, some data indicate that 10 days every 12 weeks may be sufficient to prevent endometrial hyperplasia. Estradiol in the form of a vaginal tablet or a ring is not significantly absorbed systemically and may be used safely in a woman with contraindications to estrogen therapy and symptoms of vulvovaginal atrophy.

### Osteoporosis Prevention
Postmenopausal osteoporosis is a condition that affects millions of women. Fractures, particularly hip fractures, are associated with a high incidence of morbidity and mortality and decreased QOL. Before the WHI study, only observational data were available regarding the association of HT and the reduction of fractures. The WHI was the first RCT that

**Adverse Effects of Estrogens and Progestogens**

**Estrogens**

- Common adverse effects: Nausea, Headache, Bloating, Breast tenderness, Bleeding.
- Serious adverse effects: Coronary heart disease, Stroke, Venous thromboembolism, Breast cancer, Gallbladder disease.

**Progestogens**

- Common adverse effects: Nausea, Headache, Weight gain, Bleeding, Irritability, Depression.
- Serious adverse effects: Venous thromboembolism, Decreased bone mineral density.

---

Because HT should be maintained only for the short term, traditional therapies such as bisphosphonates should be considered as first-line therapy for the prevention of postmenopausal osteoporosis, in addition to appropriate doses of calcium and vitamin D. Because of the associated risks, HT should not be prescribed solely for the prevention of osteoporosis.

**Risks of HT**

**Cardiovascular Disease**

CHD is the leading cause of death among women in the United States. Retrospective data indicated that HT was associated with a decrease in risk of CHD by 30% to 50%. However, the results of RCTs demonstrate that HT does not prevent or treat CHD in women and that it actually may cause an increase in CHD events. The HERS was the first RCT conducted in women with established CHD. This trial demonstrated an increased incidence of CHD events within the first year of treatment with HT and an increased risk of VTE and gallbladder disease. There was a trend of decreasing incidence of CHD death in years 3 to 5 that prompted a discontinuation of the study. A follow-up HERS II trial also showed no difference in CHD events after 2.7 years. The WHI was the first RCT conducted in women without established CHD. Women aged 50 to 79 years with an intact uterus were assigned to receive HT (CEE 0.625 mg + MPA 2.5 mg) daily for 8.5 years. The trial was stopped after only 5.2 years owing to an increased incidence of invasive breast cancer in women taking HT compared with those taking placebo. The WHI demonstrated an increased risk of CHD with HT compared with placebo (approximately six more cases of CHD per 10,000 women years). There also was an increased risk of stroke with HT compared with placebo (approximately seven more cases of stroke per 10,000 women years). After only 5.2 years owing to an increased incidence of invasive breast cancer in women taking HT compared with those taking placebo. The WHI demonstrated an increased risk of CHD with HT compared with placebo (approximately six more cases of CHD per 10,000 women years). There also was an increased risk of stroke with HT compared with placebo (approximately seven more cases of stroke per 10,000 women years).

The estrogen-alone arm of the WHI, which included women aged 50 to 79 years with a history of hysterectomy, continued for another 1.6 years (average follow-up 6.8 years). This arm of the study did not demonstrate an increased risk of CHD compared with placebo. However, there was an increased risk of stroke with estrogen-alone compared with placebo (approximately 12 more strokes for every 10,000 women treated per year with estrogen therapy). Women who initiated HT 10 or more years after menopause tended to have an increased cardiovascular risk compared with women who initiated therapy within 10 years of menopause.

These trials demonstrate that HT should not be prescribed for the prevention of CHD or in patients with preexisting CHD. It is important to note that the average age of women included in the HERS and the WHI trials was 67 and 63 years, respectively, and they started HT a mean of 10 years after menopause. Therefore, these trials were unable to assess the true risk in younger, potentially healthier women with fewer cardiovascular risk factors.

**Breast Cancer**

Breast cancer is the most common cancer in women in the United States. Observational data indicated an association between HT and breast cancer risk. The WHI was the first RCT to demonstrate an increased risk of invasive breast cancer among women taking HT. There were eight more cases of invasive breast cancer for every 10,000 women treated per year with HT. The increase in risk did correlate with increased age of the women, and the risk appears to be greater in those who initiate therapy within 5 years of the start of menopause. These results are overall supported by results from a follow-up study of the WHI. During approximately 11 years of follow-up, there was a significant increase in invasive breast cancer cases with combination HT compared with placebo. There were also more deaths from breast cancer and deaths overall with combination therapy than with placebo. It should be noted that any increase in risk for breast cancer appears to dissipate over 2 to 3 years after HT is discontinued. Whether HT is associated with an increased risk for breast cancer recurrence is still questionable.

Breast cancer was not increased in the estrogen-alone arm of the WHI. These data point to a possible link of progestogen with breast cancer risk. Whether or not the risk differs between continuous and sequential use of progestogens is questionable. Some evidence suggests that sequential use may be safer than taking progestogen each day.

The Million Women Study, a prospective cohort study evaluating over one million women in the United Kingdom, demonstrated an increased risk of breast cancer and breast cancer mortality in women aged 50 to 64. Breast cancer risk increased in current users in both the estrogen and progestogen arm and the estrogen only arm of the study, and the risks increased with longer duration of use.

Women with a personal history of breast cancer and possibly even a strong family history of breast cancer should avoid the use of HT and could consider alternative or nonhormonal therapies for the treatment of vasomotor symptoms.

**Venous Thromboembolism**

The WHI demonstrated an increased risk for VTE with HT compared with placebo (approximately 18 more cases of venous thromboembolic events for every 10,000 women treated per year with HT). The risk for deep vein thrombosis was also increased in the estrogen-alone arm of the WHI, but pulmonary embolism was not increased significantly. The risk of thromboembolism may be dose related, and the oral route of administration is associated with a higher risk compared with the transdermal route.

In summary, combined estrogen plus progestogen should not be used for the prevention of chronic diseases because it increases...
Other Effects of HT

QOL and Cognition Although women generally consider QOL measures when deciding whether to use HT, the effects of HT on overall QOL have been inconsistent. HT did not demonstrate a clinically meaningful effect on QOL; however, women taking HT did have a small improvement in sleep disturbances, physical functioning, and bodily pain after 1 year of therapy. Results from the HERS demonstrated that HT did improve emotional measures such as depressive symptoms, but only if women suffered from flushing at trial entry.

Observational studies suggested a potential benefit of HT on cognitive functioning and dementia. However, the Women’s Health Initiative Memory Study (WHIMS), conducted in postmenopausal women aged 65 years or older, failed to demonstrate an improvement in cognitive function and demonstrated a dementia rate, including Alzheimer disease, two times greater compared with placebo. The estrogen-alone arm of the WHIMS also demonstrated similar results. HT improves overall well-being and mood in women with vasomotor symptoms, but it has not demonstrated an improvement in QOL in women without vasomotor symptoms.

Discontinuation of HT

When treating moderate to severe postmenopausal symptoms, the benefit-to-risk ratio appears to be best when HT is started close to the time of menopause. Therapy should be tapered before discontinuation in order to limit the recurrence of hot flashes. Although vasomotor symptoms in most women will subside within 4 years, approximately 10% of women continue to experience symptoms that interfere with their QOL. Literature suggests that one of every four women needs to be reinitiated on HT due to persistent and bothersome symptoms.

Limited evidence is available to guide health care providers regarding the least disruptive way to taper HT. Slowly discontinuing HT over 3 to 6 months may be associated with less risk of symptom return. Tapering HT may be done by a dose taper or day taper. The dose taper involves decreasing the dose of estrogen over several weeks to months and monitoring closely for symptom return. If symptoms recur, the next reduction in dose should not occur until symptoms resolve or stabilize on the current dose. The day taper involves decreasing the number of days of the week that a woman takes the HT dose, for example, decreasing a daily dose of 0.3 mg estrogen to 0.3 mg estrogen 5 days a week. Again, if symptoms recur, continue on the current dose until symptoms resolve or stabilize before trying a subsequent decrease. These tapering regimens have not been studied in clinical trials and may not prove to be beneficial in individual women.

Nonhormonal and Alternative Treatments

Since publication of the WHI study, there has been an increase in the use of alternative and nonhormonal therapies for the management of menopausal symptoms, particularly for women with CHD and/or breast cancer risk factors. A wide range of therapies, both prescription and herbal, have been studied with limited success. A variety of nonhormonal and alternative therapies (Table 50–3) have been studied for symptomatic management of vasomotor symptoms. There is only weak evidence that agents are effective and also have associated adverse effects. It is important to note that randomized, placebo-controlled trials of these alternative therapies have not established safety and efficacy for prevention or treatment of menopausal symptoms.

SSRIs and venlafaxine are theorized to reduce the frequency of hot flashes by increasing serotonin in the central nervous system and by decreasing LH. Of the SSRIs, paroxetine has the most published data demonstrating a reduction in hot flashes while treating other symptomatic complaints such as depression and anxiety. Other SSRIs such as fluoxetine, citalopram, and sertraline may also be effective. These antidepressant medications offer a reasonable option for women who are unwilling to or cannot take hormonal therapies, particularly those who suffer from depression or anxiety.

Phytoestrogens are plant sterols that are structurally similar to human and animal estrogen. Soy protein is a common source of phytoestrogens. There are differences among classes of phytoestrogens and biologic potencies vary, making it difficult to recommend specific dosing. The most commonly studied phytoestrogen is the isoflavone class. Because the effect of phytoestrogens on breast cancer and other female-related cancers is unknown, these products should not be considered in women with a history of estrogen-dependent cancers. After reviewing hundreds of studies, the North American Menopause Society (NAMS) determined that soy-based isoflavones are modestly effective in relieving menopausal symptoms. The efficacy of

Patient Encounter, Part 3: Creating a Care Plan

Based on the information presented, create a care plan for this patient’s hot flashes and vaginal dryness. The plan should include:

(a) A statement identifying the problem and its severity
(b) Goals of therapy
(c) A therapeutic plan based on individual patient-specific factors
(d) Subjective and objective monitoring parameters
(e) A follow-up evaluation to assess for adverse effects and adherence to determine whether the goals of therapy have been achieved

Patient Encounter, Part 4

The patient has been in good health for the past 7 years. She reports adherence with her medications, a healthy diet and exercise routine, and her medical conditions are controlled. However, 1 month ago she was diagnosed with stage 2 breast cancer following a routine mammogram. She is concerned that her hormone therapy may have caused the breast cancer.

Educate the patient regarding the risk of breast cancer and hormone therapy.

\(^a\)Dosage adjustments recommended in patients with renal impairment.

\(^b\)Dosage adjustment recommended in patients with hepatic impairment.

Isoflavones on bone, cognitive improvement, and cardiovascular health has not been proven.

Black cohosh has been one of the most studied alternative therapies for vasomotor symptoms, but it has not demonstrated a substantial benefit over placebo. The mechanism of action, safety profile, drug–drug interactions, and adverse effects of black cohosh remain unknown. However, there have been case reports of hepatotoxicity with its use.\(^43\) In non–placebo-controlled trials conducted for 6 months or less, black cohosh demonstrated small reductions in vasomotor symptoms.\(^42\) Caution should be exercised when considering the use of this product, and it is not recommended for more than a 6-month period of time. Other alternative treatments that have been utilized include dong quai, red clover leaf, and kava. These have not been shown to be effective in the treatment of menopausal symptoms and may have significant adverse effects.\(^48\)

Gabapentin and clonidine have also been studied for the management of menopausal symptoms. In RCTs, gabapentin at doses of 900 mg/day demonstrated significant reductions in severity and frequency of hot flashes compared with placebo. Clonidine has been studied in several small RCTs at doses of 0.1 to 0.4 mg/day and has demonstrated statistically significant reductions in hot flashes.\(^45\) Overall, alternative and nonhormonal therapies are less effective in treating vasomotor symptoms than HT but do offer another option for women experiencing menopausal symptoms who cannot or are unwilling to take HT. SSRIs and phytoestrogens have the best evidence for efficacy. However, women should weigh the benefits and risks of all therapies, and discuss these options with their health care providers.

### OUTCOME EVALUATION

Evaluating the outcomes of any therapy for menopausal symptoms focuses primarily on the woman’s report of symptom resolution. Ask women to report the resolution or reduction of hot flashes, night sweats, and vaginal dryness and any improvement or change in sleep patterns. Also ask women taking hormonal therapies to report any breakthrough bleeding or spotting. If abnormal or heavy bleeding occurs, refer the woman to her primary care provider. Monitor subjective parameters such as adverse effects and adherence to the therapy regimen. In addition, monitor objective parameters, including blood pressure, at every outpatient visit; encourage yearly clinical breast examinations, mammograms, lipid panel, and thyroid-stimulating hormone (TSH) determination, particularly for women with hypothyroidism on thyroid therapy, and conduct a BMD test every 2 to 5 years as indicated. Also perform endometrial studies, as necessary, in women with undiagnosed vaginal bleeding. Lastly, evaluate the patient’s overall QOL. Because the management of menopause is largely symptomatic, it is important to document symptoms at the beginning of therapy and monitor symptom improvement and potential adverse effects at each visit. Frequent follow-up, proper monitoring, and education will help to ensure that the woman achieves optimal results from any therapy chosen to treat menopausal symptoms.

### Patient Encounter, Part 5

It has been 6 months since this patient completed chemotherapy and radiation for breast cancer. She presents to her PCP for follow-up with a chief complaint of recurrent hot flashes. She also complains of recurrent vaginal dryness but denies insomnia.

Recommend the most appropriate therapy for her recurrent hot flashes and vaginal dryness.
**Patient Assessment:**
- Obtain a thorough medication history, including the use of over-the-counter and herbal products.
- Rule out other medical conditions that could be contributing to symptoms and manage those conditions prior to initiating therapy for symptoms.
- Evaluate for the presence of vasomotor symptoms and document findings.

**Therapy Evaluation:**
- If the patient is experiencing bothersome vasomotor symptoms, consider the use of HT only after assessing for risk factors for heart disease and breast cancer.
- If vasomotor symptoms are tolerable and/or the patient has risk factors for heart disease and/or breast cancer, consider alternative, nonhormonal treatments for vasomotor symptoms.

**Care Plan Development:**
- Discuss lifestyle or behavioral interventions that may help to alleviate vasomotor symptoms.
- Discuss methods of HT administration, and decide in conjunction with the health care provider which one will work best for her.
- Recommend the appropriate dose of HT, and use the lowest effective dose for the shortest duration of time.
- Discuss proper administration, potential adverse effects, and expectations of HT.
- Discuss the importance of adhering to the medication regimen.

**Follow-Up Evaluation:**
- Monitor for a reduction in vasomotor symptoms, vaginal dryness, and improvement in sleep. Also monitor for breakthrough bleeding and spotting, adverse effects of HT, and improvement in QOL.
- Monitor the following objective parameters: blood pressure at every outpatient visit, yearly lipoprotein panels, yearly breast examinations and mammograms, yearly TSH determinations, and endometrial studies in women with undiagnosed vaginal bleeding.
- Assess symptoms every 6 to 12 months, and consider tapering the HT dose and discontinuing treatment after 5 years. If vasomotor symptoms return, determine whether a longer tapering schedule is warranted or if long-term treatment is necessary. If treatment beyond 5 years is necessary, consider switching to a nonhormonal product.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:
1. Explain the pathophysiology of erectile dysfunction (ED).
2. Recognize risk factors and medications associated with the development of ED.
3. Identify the goals of therapy when treating ED.
4. Describe current nonpharmacologic and pharmacologic options for treating ED, and determine an appropriate first- and second-line therapy for a specific patient.
5. Identify patients with significant cardiovascular risk and recommend an appropriate treatment approach for their ED.
6. Compare and contrast the benefits and risks for the current phosphodiesterase (PDE) inhibitors.
7. Assess reasons for PDE failure and determine an optimal approach to improve treatment efficacy.

INTRODUCTION

Erectile dysfunction (ED) is defined as the persistent inability to achieve or maintain an erection sufficient for sexual intercourse. ED is the most prominent sexual problem in men, and it can lead to lower quality of life and self-esteem. Patients may also develop libido or ejaculatory disorders, but these are not considered ED.

EPIDEMIOLOGY AND ETIOLOGY

ED increases with age. Few men report erection problems before age 50, but ED increases to 20% to 40% in men aged 60 to 69 years and 50% to 100% in men older than 70 years. The increase in incidence could be due to physiologic changes that occur with aging, the onset of chronic disease states associated with ED, increased medication use, lifestyle factors, or a combination of the above.

PATHOPHYSIOLOGY

The penis consists of three components, two dorsolateral corpora cavernosa and a ventral corpus spongiosum that surrounds the penile urethra and distally forms the glans penis. In the flaccid state, arterial and corporal smooth muscles are tonically contracted, and a balance exists between blood flow into and out of the corpora. With sexual stimulation, nerve impulses from the brain travel down the spinal cord triggering a reduction in sympathetic tone and an increase in parasympathetic activity. This leads to an increased production of nitric oxide (NO). NO enhances the activity of guanylate cyclase, which results in increased production of cyclic guanosine monophosphate (cGMP). Vasoactive peptide and prostaglandins E₁ and E₂ stimulate increased production of cyclic adenosine monophosphate (cAMP). Both cAMP and cGMP reduce calcium concentrations within smooth muscle cells of the penile arteries and the sinusoidal spaces, leading to smooth muscle relaxation and increased blood flow. As the spaces become engorged, intracavernosal pressure increases, subtunical venules are compressed by the tunica albuginea, and the penis becomes rigid and elongated (Figure 51–1).

Detumescence occurs with sympathetic discharge after ejaculation. Sympathetic activity induces smooth muscle contraction of arterioles and vascular spaces leading to a reduction in blood inflow, decompression of the sinusoidal spaces, and enhanced outflow.

Testosterone also plays a significant albeit complex role in erectile function. In addition to stabilization of intracavernosal levels of NO synthase, the enzyme responsible for triggering the NO cascade, testosterone is responsible for much of a man’s libido. Interestingly, some patients with low or borderline-low serum concentrations will have normal erectile function, whereas those with adequate levels may have dysfunction.

Normal penile erections are complex events that require the full function of the vascular, neurologic, hormonal and psychogenic systems. Anything that affects the function of these systems may lead to ED. ED can be classified as organic, psychogenic, or a mixture of these. Organic dysfunction includes abnormalities in the vascular, hormonal, or neurologic systems or may be medication-induced (Tables 51–1 and 51–2). It is estimated that 25% of ED cases are due to medications. Note that many of the risk factors for ED are the same as those for cardiovascular (CV) disease, including hypertension, diabetes, dyslipidemia, smoking, obesity, metabolic syndrome, and sedentary behavior. In many patients, ED is the first indication of the endothelial dysfunction associated with CV disease, with two-thirds of patients with coronary artery disease having symptoms of ED before the onset of coronary symptoms. The presence of ED risk factors...
FIGURE 51–1. Mechanism of erection and sites of action of various treatment modalities for erectile dysfunction (ED). Penile erection is achieved through relaxation of smooth muscle cells lining arterial vessels and sinusoidal spaces in the corpora cavernosa, which leads to increased arterial inflow and pressure, decreased venous outflow, and increased intracavernosal pressure. Smooth muscle relaxation is mediated by intracellular generation of cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP) via activation of guanylate cyclase by nitric oxide. Treatment modalities for ED include oral phosphodiesterase type 5 (PDE-5) inhibitors, which inhibit the breakdown of cGMP, and local vasoactive agents. Nitric oxide–cGMP signaling in cavernous smooth muscle. (cGMP, cyclic guanosine monophosphate; GTP, guanosine triphosphate; PDE, phosphodiesterase 5; PKG, protein kinase G.) (Reproduced, with permission, from Setter SM, Iltz JL, Fincham JE, Campbell RK, Baker DE. Phosphodiesterase 5 inhibitors for erectile dysfunction. Ann Pharmacother. 2005;39(7-8):1286–1295.)

leads to the assumption that the patient has organic dysfunction. Most commonly, medical conditions that impair arterial flow into or out of the erectile tissue or affect the innervation will be strongly associated with ED. Patients with diabetes mellitus have exceptionally high rates of ED as a result of vascular disease and neuropathy. Additionally, a relationship has been found between

Possible Signs and Symptoms

- Embarrassment
- Anxiousness
- Anger
- Marital difficulties
- Low self-confidence or morale; depression
- Full inability to achieve erections
- Ability to achieve partial erections, but not suitable for intercourse
- Erections sufficient for intercourse, but early detumescence
- The problem may have a slow or acute onset, or may wax and wane

Diagnosis

ED may be the presenting symptom of other chronic disease states. The following should be performed to determine areas that can cause or exacerbate ED and to assess the patient’s ability to safely perform intercourse.

- Medical history with emphasis on cardiovascular and psychiatric disorders, diabetes, trauma, and surgical procedures
- Social history including nutrition and history of smoking, recreational drug use, exercise, and alcohol consumption
- Medication history including prescription, nonprescription, and dietary supplements

Physical Examination

- Review for hypogonadism (gynecomastia, testicular atrophy, reduced body hair, increase in body fat)
- Digital rectal examination to determine whether prostate is enlarged
- Vital signs
- Abnormalities of the penis or impaired vasculature and nerve function to the penis

Labs

- Fasting glucose or HbA₁c
- Serum testosterone if signs of hypogonadism
- Fasting lipid panel
- Further cardiac testing if warranted

Determine Severity

- Use an abridged, five-item version of the International Index of Erectile Dysfunction (IIEF-5) as a diagnostic tool.
- How do you rate your confidence that you could get and keep an erection?
- When you had erections with sexual stimulation, how often were your erections hard enough for penetration?
- During sexual intercourse, how often were you able to maintain your erection after you had penetrated (entered) your partner?
- How difficult was it to maintain your erection to completion of intercourse?
- When you attempted sexual intercourse, how often was it satisfactory for you?

Questions scored 1 to 5, very low to very high, respectively. Score of 21 or less indicates ED likely.

CLINICAL PRESENTATION AND DIAGNOSIS OF ED

The introduction of oral medications and direct-to-consumer advertising has made patients feel more comfortable approaching practitioners for treatment advice. Despite this, some patients may only discuss their dysfunction when questioned directly by their provider or if their partner initiates the interaction.

TREATMENT

Desired Outcomes

ED is not a life-threatening condition, but if left untreated, it can be associated with depression, loss of self-esteem, poor self-image, and marital discord. The primary goal of therapy is achievement of erections suitable for intercourse and improvement in patient and partner quality of life. Additionally, the ideal therapy should have minimal side effects, be convenient to administer, have a quick onset of action, and have few or no drug interactions.

General Approach to Treatment

Before initiating treatment for ED, a physical examination and thorough medical, social, and medication histories with emphasis on cardiac disease must be taken to assess for ability to safely perform sexual activity and to assess for possible drug interactions. In patients with intermediate or high cardiovascular risk, additional testing should occur to determine whether sexual activity is safe.

Treatment options for ED include medical devices, pharmacologic treatments, lifestyle modifications, surgery, and psychotherapy. Reversible causes of ED should be identified first and treated appropriately.

When determining the best treatment for an individual, the role of the clinician is to inform the patient and his partner of all available options while understanding his medical history, desires, and goals. The choice of treatment is primarily left up to the couple, but most often treatment is initiated with the least invasive options such as oral phosphodiesterase (PDE) inhibitors and vacuum erection devices (VEDs). Ultimately, the choice of therapy should be individualized, taking into account patient
and partner preferences, concomitant disease states, response, administration route, cost, tolerability, and safety. Common drug treatment regimens for ED are listed in Table 51–3.

Nonpharmacologic Therapy

Lifestyle Modifications Lifestyle modifications should always be addressed in the management of ED. A healthy diet, increase in regular physical activity, and weight loss are associated with higher International Index of Erectile Function (IIEF) scores and an improvement in erectile function. The clinician should also recommend smoking cessation, reduction in excessive alcohol intake, and discontinuation of illicit drug use.

Psychotherapy Psychotherapy is an appropriate treatment approach for patients with psychogenic or mixed dysfunction. Counseling may include simple sex education and improved partner communication in addition to cognitive and behavioral therapy. Psychotherapy may help relieve anxiety and eliminate unrealistic expectations. Effectiveness is not well documented for organic dysfunction unless combined with pharmacotherapy.

Patient Encounter 1, Part 1

A 68-year-old man with type 2 diabetes, hypertension, chronic kidney disease, and dyslipidemia returns to your clinic for follow-up on his chronic disease states. When reviewing his history, he describes problems with his erections as well as an increase in nocturnal urination and dribbling when voiding. After further questioning, you determine that his erectile dysfunction has progressively gotten worse over the last year. He is quite emotional and states that the problem is distressing and has caused significant marital discord. He wonders about “those ads on television” suggesting a pill.

Based on the available information, how would you classify his erectile dysfunction (ED)?

What additional information do you need before establishing an appropriate treatment regimen and determining his ability to safely perform intercourse?

Table 51–3

Testosterone Supplementation

| Intramuscular | Testosterone cypionate | Depo-Testosterone | 50–400 mg every 2–4 weeks | Once weekly |
| Topical       | Testosterone enanthate | Delatatestyl      | 50–400 mg every 2–4 weeks | Once weekly |
|               | Testosterone patch     | Androderm         | 2–4 mg/day applied to back, abdomen, upper arms, or thighs | Once daily |
|               | Testosterone gel        | AndroGel 1%, Testim, Vogelko | 5–10 g gel per day (50–100 mg testosterone) to shoulders, upper arms, abdomen (AndroGel 1% only) | Once daily |
|               |                         | AndroGel 1.62% Natesto | 40.5–81 mg/day to shoulders or upper arms | Once daily |
|               |                         | Fortesta          | 11 mg every 8 hours (2 pump actuations, 1 per nostril) | 3 times daily |
|               |                         | Axiron            | 10–70 mg/day to thigh | Once daily |
|               |                         | Striant           | 30–120 mg/day to axilla | Once daily |
| Buccal        | Testosterone solution   | Axiron            | 30 mg every 12 hours to gum region above incisor; rotate to alternate sides with each dose | 2 times daily |
| Subcutaneous implantable pellet | Testosterone | Testopel | 150–450 mg (150 mg for every 25 mg testosterone propionate required weekly) | Every 3–6 months |

MUSE, medicated urethral system for erection.

*a*Use the lowest effective dose to limit adverse effects.

*b*Initial dose must be titrated in physician’s office.
Vacuum Erection Devices Vacuum erection devices (VEDs) induce erections by creating a vacuum around the penis; the negative pressure draws blood into the penis by passively dilating arteries and engorging the corpora. The erection is maintained with a constriction band placed at the base of the penis to reduce venous outflow (Figure 51–2). VEDs may be used as often as desired, but it is recommended that the constriction band not be left in place longer than 30 minutes at a time.

Onset of action is slow, which limits spontaneity. In addition, patients and partners may complain of a cold, lifeless, discolored penis that has a hinge-like feel. Painful ejaculation or inability to ejaculate are additional adverse effects. VEDs are relatively contraindicated in persons with sickle cell disease and should be used with caution in those on oral anticoagulants or who have bleeding disorders due to the increased possibility of priapism.

VEDs are highly effective treatment modalities for ED and are considered a first- or second-line therapy. Efficacy rates are as high as 90% in obtaining an erection sufficient for coitus. Although satisfaction rates are as high as 94%, the discontinuation rate after 2 years is close to 50%. A double pumping technique in which the vacuum is applied for a 1 to 2 minutes, removed, then reapplied for another 3 to 4 minutes may improve comfort levels and rigidity. Higher efficacy rates can also be achieved by combining VEDs with other therapies. VEDs are generally more acceptable to older patients in stable relationships and with infrequent sexual encounters.

Prostheses Penile prostheses are semirigid malleable or inflatable rods, which are inserted surgically into the corpus cavernosa (see Figure 51–2). The malleable rods are rigid at all times, but may be bent into position by the patient when desired. The inflatable prostheses remain flaccid until the pump within the scrotum moves fluid from a reservoir to the cylinders within the penis. Detumescence is achieved when the fluid is then transferred back to the reservoir by activating a release button.

Patient satisfaction rates can be as high as 100%, with partner satisfaction rates slightly lower, but prostheses are the most invasive treatment available so are considered last-line therapy. Infection occurs in 1% to 3% of first-time prostheses. Semirigid malleable rods may interfere with urination, are difficult to conceal, and have a higher likelihood of erosion.

**Pharmacologic Therapy**

**Phosphodiesterase Type 5 Inhibitors** Avanafil, sildenafil, tadalafil, and vardenafil act by selectively inhibiting phosphodiesterase (PDE) type 5, which is responsible for degradation of cGMP. With prolonged cGMP activity, smooth muscle relaxation is induced, leading to an erection (see Figure 51–1). However, the PDE inhibitors are only effective in the presence of sexual stimulation to drive the NO/cGMP system, making them facilitators of an erection, not initiators.

**Effectiveness of the four available PDE inhibitors is essentially comparable, but differences exist in onset, duration of action, absorption with a fatty meal and, to a small degree, incidence of side effects and drug interactions (Table 51–4).** Review of available data for each individual agent shows a 60% to 75% response rate depending on the dose of agent used and the etiology of dysfunction. Response rates tend to be lower in patients with radical prostatectomy as well as those with diabetes, severe nerve damage, or severe vascular disease. Although efficacy rates appear to be similar between agents, there are some data to suggest that continuation rates are higher and patient preference greater with tadalafil. The PDE inhibitors are considered first-line therapies due to high efficacy rates, convenience of dosing, and minimal severe adverse effects.

The most dramatic difference among the four agents is tadalafil’s extended duration of action (18 hours), earning it the nickname “the weekender drug.” All are approved for as-needed dosing. Tadalafil has also been approved for use as a daily medication at a lower dose (2.5–5 mg) than the as-needed dose with similar efficacy.

The most common side effects experienced with PDE inhibitors include headache, facial flushing, nasal congestion, dyspepsia, myalgia, back pain, and, rarely, priapism. Vardenafil and sildenafil may also cause blurred vision, difficulty in discriminating blue from green, blush tones in vision, or difficulty seeing in dim light due to cross-reactivity with PDE 6 in the retina. Labeling for all PDE inhibitors includes a warning about rare nonarteritic ischemic optic neuropathy (NAION) in which blood flow is blocked to the optic nerve. If patients experience sudden or decreased vision loss, they should call a health care provider immediately. PDE inhibitors have also been associated with acute hearing impairment although a causal relationship has not been established.

**Due to the coexistence of ED and coronary artery disease, a management approach was developed to give recommendations for the use of PDE inhibitors as well as to determine the safety of intercourse in patients with CV disease (Table 51–5). In addition to the inherent risk of renewing sexual activity, PDE inhibitors can lead to significant hypotension. Patients taking organic nitrates are at highest risk, as these drugs potentiate the drop in blood pressure. All four PDE inhibitors are absolutely contraindicated in patients taking any form of nitrate, whether scheduled or sublingual for acute situations. Additionally, caution should be used when combining a PDE inhibitor with α-blockers. Vardenafil contains a precautionary statement about the possibility of QT prolongation. Drug interactions and cautions vary slightly between agents and are described in Table 51–4.**

**Figure 51–2.** Available devices and prostheses used to treat ED. (From Wagner G, Saenz de Tejada I. Update on male erectile dysfunction. BMJ 1998;316:678–682.)

CYP, cytochrome P-450 isoenzyme.

<sup>a</sup>Moderate renal impairment = creatinine clearance (CrCl) 31 to 50 mL/min (0.51–0.83 mL/s).

<sup>b</sup>Severe renal impairment = CrCl less than 30 mL/min (0.50 mL/s).

<sup>c</sup>Mild to moderate only—contraindicated in severe disease.

<sup>d</sup>Selective α<sub>-</sub>blockers (such as alfuzosin, silodosin, and tamsulosin) are appropriate in combination. If nonselective, initiate with lowest dose possible.

<sup>e</sup>Vardenafil can cause QT-interval prolongation; this effect in combination with certain antiarrhythmic agents can lead to life-threatening arrhythmias.

Up to a third of patients will not respond to therapy with PDE inhibitors. To achieve the greatest effect, patients must be fully informed of onset and duration of effect, impact of high-fat meals, the need for sexual stimulation, and explanation that a single trial is not adequate with a medication and specific dose may be needed before successful intercourse results.<sup>f</sup>

**Alprostadil** Alprostadil is a prostaglandin E<sub>1</sub> analog that induces an erection by stimulating adenyl cyclase, leading to increased cAMP, smooth muscle relaxation, rapid arterial inflow, and increased penile rigidity. Alprostadil is available as an intracavernosal injection (Caverject or Edex) or a transurethral suppository (MUSE, medicated urethral system for erection), with the injectable dose showing greater efficacy (Figure 51–3).<sup>4,5</sup> Both forms of alprostadil are considered more invasive than oral medications and VEDs and are therefore second-line therapies.

MUSE consists of a urethral pellet of alprostadil with an applicator. Onset of action is within 5 to 10 minutes and it is effective for 30 to 60 minutes. Initial dose titration should occur in a physician’s office to ensure correct dose and prevent adverse events. Success rates in clinical trials are between 43% and 69%, but typical use has resulted in less successful results in postmarketing studies.<sup>1,2,3</sup> Aching in the penis, testicles, legs, and perineum; warmth or burning sensation in the urethra, minor urethral bleeding or spotting, priapism, and light-headedness are all possible adverse effects. In addition, partners may experience burning or itching, and use is contraindicated with a pregnant partner unless using a condom.

Intraurethral alprostadil injection is the more effective route and is the only FDA-approved injection for ED. The onset of action is similar to transurethral alprostadil, but duration varies with dose and must be titrated in a physician’s office to achieve an erection lasting no more than 1 hour. Injections should be performed into one side directly into the corpus cavernosum, and then the penis should be massaged to distribute the drug to both corpora. Education is extremely important with intracavernosal injections. Patients must be adequately informed of technique, expectations, side effects, and when to seek help. Intracavernosal injections are effective in up to 80% of patients, but side effects, lack of spontaneity, and fear of needles limit their...

Patient Encounter 1, Part 2

PMH: Type 2 diabetes for 15 years; not controlled due to his stressful profession; he often works late, eats on the run, and has no time for exercise. Chronic kidney disease stage 3. Hypertension for 8 years, currently controlled. Dyslipidemia for 8 years, currently controlled

SH: Works long hours as a business executive; drinks alcohol only occasionally; has a 20-pack per year smoking history

Meds: Metformin 1000 mg orally twice daily; metoprolol XL 50 mg orally once daily; hydrochlorothiazide 25 mg once daily; simvastatin 40 mg orally once daily

ROS: (−) Morning, nocturnal, or spontaneous erections suitable for intercourse; (+) nocturia, urgency, incomplete bladder emptying, dribbling; (−) symptoms of prostatitis; (−) chest pain or anginal symptoms; (+) significant life stressors; (+) mild pain in feet

PE:

VS: BP 135/78, P 85, RR 18, Wt 249 lb (113 kg), Ht 70 in (178 cm)

CV: Normal examination

Genital/Rectal: Normal scrotum and testicles w/o masses; penis without discharge or curvature; DRE reveals enlarged prostate

Labs: lipid panel: total cholesterol, LDL, HDL, triglycerides at goal; HbA1c, 8% (0.08; 64 mmol/mol Hgb), total testosterone 700 ng/dL (24 nmol/L), PSA 1.2 ng/ml (1.2 mcg/L), BUN 25 mg/dL (8.9 mmol/L); SCR 1.7 mg/dL (150 μmol/L)

Given this additional information, what are his risk factors for ED?

Identify treatment goals for this patient.

Perform a cardiovascular risk assessment to determine risk.

What pharmacologic and nonpharmacologic alternatives are available for this patient?

Which of the available options will be your treatments of choice based on concomitant disease states and medications, degree of invasiveness, side effects, ease of use, and side-effect profile?

What are the safety and efficacy monitoring parameters for the chosen treatment?

widespread use as first-line therapy, and therefore this therapy is most appropriate for patients in long-term stable relationships.\textsuperscript{1,4} Adverse effects include pain with injection, bleeding or bruising at the injection site, fibrosis, or priapism. Use with caution in patients with sickle cell disease, those on anticoagulants, or those who have bleeding disorders, due to an increased risk of priapism and bleeding.

**Testosterone Supplementation** \textsuperscript{\textbf{KEY CONCEPT}} Androgens are important for general sexual function and libido, but testosterone supplementation is only indicated in patients with documented low serum testosterone levels. In patients with hypogonadism, testosterone replacement is the initial treatment of choice, as it corrects decreased libido, fatigue, muscle loss, sleep disturbances, and depressed mood. However, testosterone is contraindicated in patients with prostate cancer, erythrocytosis, uncontrolled heart failure or sleep apnea.

Testosterone supplementation may improve ED symptoms, but is not universally effective. Initial supplementation should occur for 3 months with reevaluation and the addition of another ED therapy if needed at that time. Dosage forms include intramuscular, an implanted pellet, topical patches or gel, and a buccal tablet.

Injectable testosterone cypionate and enanthate offer the most inexpensive replacement option. There are several drawbacks associated with parenteral testosterone, including the need to administer deep intramuscular injections every 2 to 4 weeks. Concentrations of hormone are well above physiologic values within the first few days, and then decline and eventually dip below physiologic levels prior to the next dose. These changes in concentration may lead to mood swings and a reduced sense of well-being.\textsuperscript{19} Implantable subcutaneous testosterone pellets are a longer-acting and convenient alternative which are placed every 3 to 6 months.

Treatment with topical products is attractive to patients due to convenience, but they tend to be more expensive than the injections. Testosterone patches and gels are administered daily and result in serum levels within the physiologic range during the 24-hour dosing period.\textsuperscript{19} Care must be taken with the use of the gel to prevent transfer of testosterone to children and females by washing hands thoroughly, allowing the site to dry, and covering immediately. Newer formulations for the axilla and thigh may reduce this risk. The most common side effects of topical testosterone are dermatologic reactions.

Oral testosterone products are also available for supplementation. Unfortunately, testosterone has poor oral bioavailability and undergoes extensive first-pass metabolism. Alkylated derivatives such as methyltestosterone and fluoxymesterone have been formulated, but this modification makes them considerably more hepatotoxic and therefore undesirable.

An alternative to the oral route is the buccal mucoadhesive system. This system adheres to the inside of the mouth and testosterone is absorbed through the oral mucosa and delivered to the systemic circulation with no first-pass effect. Side effects unique to this dosage form include oral irritation, bitter taste, and gum edema.

General side effects of testosterone include gynecomastia, dyslipidemia, polycythemia, and acne. Weight gain, hypertension, edema, and exacerbations of heart failure also occur due to sodium retention. Before initiating testosterone,

**Patient Encounter 2**

A 62-year-old man with a history of hypertension, prostatectomy 1 year ago, and recent diagnosis of ED. When in the office for a routine follow-up, he states the pill recently prescribed for his ED is not “doing the trick” so he has not been using it. He also complains that he is tired all the time, does not have much of a libido anymore, and is gaining weight.

**Meds:** losartan/hydrochlorothiazide 50/25 mg orally once daily, vardenafil 5 mg orally as needed

**ROS:** (−) Morning, nocturnal, or spontaneous erections suitable for intercourse; (−) nocturia, or urgency

**PE:**

**VS:** BP 132/74, P 82, Wt 214 lb (97 kg), Ht 75 in (191 cm)

**Labs:** Lipid panel, complete metabolic panel within normal limits

Based on the information provided, what is your assessment of the patient’s ED?

What should be recommended as the next step in treatment of his ED?
the patient should undergo evaluation for benign prostatic hypertrophy and prostate cancer. Routine follow-up includes yearly prostate-specific antigen, digital rectal examination, and hemoglobin and liver function, in addition to assessment of response.

OUTCOME EVALUATION
Successful therapy for ED results in an increase in erections suitable for intercourse and, most importantly, in an improvement in the patient’s quality of life. Ideally, the therapy chosen is free of significant adverse effects, discomfort, and inconvenience. Laboratory evaluation and a physical examination are not necessary for evaluation of effectiveness but may be necessary for adverse event monitoring.

Evaluate satisfaction and effectiveness after a 4-week trial. Some therapies will require multiple visits over the long term to determine the correct dose and to detect adverse effects. If the initial therapy is not effective, the patient must be further evaluated to determine whether the initial assessment of comorbid disease states, type of dysfunction, and patient goals were appropriate. After providing further education and determination of realistic goals, providers may then increase the dose of medication, switch to another therapy, or add a therapy if indicated.

Abbreviations Introduced in This Chapter
- cAMP: Cyclic adenosine monophosphate
- cGMP: Cyclic guanosine monophosphate
- ED: Erectile dysfunction
- IIEF: International Index of Erectile Function
- MUSE: Medicated urethral system for erection
- NAION: Non-arteritic ischemic optic neuropathy
- PDE: Phosphodiesterase
- VED: Vacuum erection device

REFERENCES
LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying the symptoms and signs of benign prostatic hyperplasia (BPH).
2. Recognize the symptoms and signs of BPH in individual patients.
3. List the desired treatment outcomes for a patient with BPH.
4. Identify factors that guide selection of a particular α-adrenergic antagonist for an individual patient.
5. Compare and contrast α-adrenergic antagonists versus 5α-reductase inhibitors in terms of mechanism of action, treatment outcomes, adverse effects, and interactions when used for management of BPH.
6. Describe the indications, advantages, and disadvantages of various combination drug regimens for BPH that include an α-adrenergic antagonist, 5α-reductase inhibitor, anticholinergic agent, tadalafil, or mirabegron.
7. Describe the indications for surgical intervention of BPH.
8. Formulate a monitoring plan for a patient on a given drug treatment regimen based on patient-specific information.
9. Formulate appropriate counseling information for patients receiving drug treatment for BPH.

INTRODUCTION

The prostate is an organ, which is of the shape and size of a horse chestnut, that encircles the portion of the proximal posterior urethra that is located at the base of the urinary bladder. The prostate produces secretions, which are part of the ejaculate.

Benign prostatic hyperplasia (BPH) is the most common benign neoplasm in males who are at least 40 years of age. BPH can produce lower urinary tract symptoms (LUTS) that are consistent with impaired emptying of urine from and defective storage of urine in the bladder. Medications are a common mode of treatment to reduce symptoms and/or delay complications of BPH. For this reason, clinicians should be knowledgeable about the medical management of this disease.

EPIDEMIOLOGY AND ETIOLOGY

BPH is present as histologic disease in many elderly males. The prevalence increases with advancing patient age. However, of patients with microscopic BPH disease, only about 50% of patients develop an enlarged prostate on digital palpation and 25% of patients exhibit clinical voiding symptoms. It is estimated that 8% of males 40 years of age, increasing to 35% of men 60 to 69 years of age, have voiding symptoms consistent with BPH, and 20% to 30% of all male patients who live to the age of 80 years will require a prostatectomy for severe voiding symptoms of BPH.

Two chief etiologic factors for BPH include advanced patient age and the stimulatory effect of androgens.

- Prior to 40 years of age, the prostate in the adult male stays the same size, approximately 15 to 20 g. However, in males who have reached 40 years of age, the prostate undergoes a growth spurt, which continues as the male advances in age. Enlargement of the prostate can result in clinically symptomatic BPH.
- The testes and adrenal glands produce 90% and 10%, respectively, of circulating testosterone. Testosterone enters prostate cells, where predominantly Type II 5α-reductase converts testosterone to dihydrotestosterone, which combines with a cytoplasmic receptor. The complex enters the nucleus and induces changes in protein synthesis that promote glandular tissue growth of the prostate. Thus 5α-reductase inhibitors (eg, finasteride and dutasteride) directly interfere with one of the major etiologic factors of BPH.
- The prostate is composed of two types of tissue: (a) glandular or epithelial tissue, which produces prostatic secretions, including prostate-specific antigen (PSA), and (b) muscle or stromal tissue, which can contract around the urethra and bladder outlet when stimulated. Whereas androgens stimulate glandular tissue growth, androgens have no direct effect on stromal tissue. Stromal tissue growth may be stimulated by estrogen. Because testosterone is converted to estrogen in peripheral tissues in males, testosterone may be...
associated indirectly with stromal hyperplasia. Stromal tissue is innervated by \( \alpha_\lambda \)-receptors. When stimulated, prostatic stroma contracts around the urethra, narrowing the urethra and causing obstructive voiding symptoms.

**PATHOPHYSIOLOGY**

**KEY CONCEPT** LUTS and signs of BPH are due to static, dynamic, and/or detrusor factors. The static factor refers to anatomic obstruction of the bladder neck caused by an enlarged prostate gland. As the gland grows around the urethra, the prostate occludes the urethral lumen. The dynamic factor refers to excessive stimulation of \( \alpha_\lambda \)-adrenergic receptors in the smooth muscle of the prostate, urethra, and bladder neck, which results in smooth muscle contraction. This reduces the caliber of the urethral lumen. The detrusor factor refers to bladder detrusor muscle hypertrophy in response to prolonged bladder outlet obstruction. To further explain, detrusor muscle fibers undergo hypertrophy so that the bladder can generate higher pressure to overcome bladder outlet obstruction and empty urine from the bladder. The hypertrophic detrusor muscle becomes irritable, contracting abnormally in response to small amounts of urine in the bladder. If obstruction is not treated, the bladder muscle will decompensate and be unable to empty completely; the postvoid residual urine volume (PVR) will increase.

In an enlarged gland, the epithelial/stromal tissue ratio is 1:5. Androgens stimulate epithelial, but not stromal tissue hyperplasia. Hence, androgen antagonism does not induce a complete reduction in prostate size to normal. This explains one of the limitations of the clinical effect of 5α-reductase inhibitors.

Stromal tissue is the primary locus of \( \alpha_\lambda \)-adrenergic receptors in the prostate. An estimated 98% of the \( \alpha \)-adrenergic receptors in the prostate are found in prostate stromal tissue. Of the \( \alpha_\lambda \)-receptors found in the prostate, 70% of them are of the \( \alpha_\lambda \_\alpha \) subtype and the remainder are of the \( \alpha_\lambda \_\beta \) and \( \alpha_\lambda \_\gamma \) subtypes. This explains why \( \alpha \)-adrenergic antagonists are effective for managing symptoms of BPH.

Symptoms of BPH are classified as obstructive or irritative. Obstructive symptoms result from failure of the urinary bladder to empty urine when the bladder is full. The patient will complain of a decreased force of the urinary stream, urinary hesitation, dribbling, intermittency, a sensation that the bladder is not empty even after voiding, and straining to empty the bladder. Irritative symptoms, including urinary frequency, nocturia, and urgency, result from the failure of the urinary bladder to store urine until the bladder is full. The natural history of untreated BPH is unclear in patients with mild symptoms. It is estimated that up to 38% of untreated men with mild symptoms will have symptom improvement over a 2.5- to 5-year period. It may be that such patients attribute their symptoms to aging, grow tolerant of their symptoms, or adopt behavioral changes in their lifestyle that minimize their voiding symptoms. On the other hand, a significant portion of patients with mild symptoms will likely experience disease progression. Patients with moderate to severe symptoms can experience a decreased quality of life as daily activities are adjusted because of lower urinary tract voiding symptoms. Also, such patients may develop complications of BPH, which include acute refractory urinary retention, renal failure, urinary tract infection, urinary incontinence, bladder stones, large bladder diverticuli, and recurrent gross hematuria. Predictors of disease progression include an enlarged prostate of at least 30 g (1.05 oz) or PSA of 1.4 ng/mL (1.4 mcg/L) or greater. Finally, erectile dysfunction commonly develops in patients with BPH. Effective treatment of BPH symptoms often improves sexual function without initiating specific treatment for erectile dysfunction.

**TREATMENT**

**Desired Outcomes**

- **KEY CONCEPT** Reducing or eliminating obstructive and irritative voiding symptoms. Drug treatment with an \( \alpha \)-adrenergic antagonist or 5α-reductase inhibitor is expected to decrease the American Urological Association (AUA) Symptom Score by 30% to 50% (or at least by three or more points), improve peak and mean urinary flow rate by 1 to 3 mL/s, and decrease postvoid residual urine volume (PVR) to normal (less than 50 mL total) when compared with pretreatment baseline values. The AUA Symptom Score may not correlate with response to therapy.

- Slowing disease progression. When compared with baseline, symptoms and serum blood urea nitrogen (BUN) and creatinine should improve, stabilize, or decrease to the normal range with treatment.

- Preventing disease complications and reducing the need for surgical intervention.

- Avoiding or minimizing adverse treatment effects.

- Providing economical therapy.

- Maintaining or improving quality of life.

**General Approach to Treatment**

Until recently, the principal approach to treatment focused on reducing BPH symptoms (Figure 52–1, Tables 52–1, 52–2, and 52–3). However, treatment should also slow disease progression and decrease complications of BPH.

- **KEY CONCEPT** For patients with mild symptoms (AUA Symptom Score of 7 or less) that the patient does not consider to be bothersome, watchful waiting is a reasonable approach to treatment. The patient is instructed to schedule return visits to the clinician every 6 to 12 months. At each visit, the patient’s symptoms are reassessed using the AUA Symptom Scoring Index, and results are compared with baseline (see Table 52–1). In addition, the patient is educated about implementing nonpharmacologic measures to reduce voiding symptoms (see section on Nonpharmacologic Therapy) and avoiding factors that worsen obstructive and irritative voiding symptoms (Table 52–4). The digital rectal examination (DRE) is repeated annually. If the patient’s symptoms are unchanged, then watchful waiting is continued. If the patient’s symptoms worsen, then specific treatment is initiated. Watchful waiting is effective in approximately 65% of patients after 5 years.
Clinical Presentation and Diagnosis of BPH

General
Patients may or may not be in acute distress. In early stages of disease, the patient may complain of obstructive voiding symptoms. If untreated, the disease may progress and the patient may complain of irritative voiding symptoms or acute urinary retention, which is painful due to maximal distention of the urinary bladder. Also, the patient may be symptomatic of disease complications, including urosepsis, pyelonephritis, cystitis, or overflow urinary incontinence.

Symptoms
Patients may complain of obstructive voiding symptoms (eg, urinary hesitancy, decreased force of urinary stream, straining to void, incomplete bladder emptying, dribbling, and intermittency) and/or irritative voiding symptoms (eg, urinary frequency, nocturia, and urgency). Severity of symptoms should be assessed by the patient using a standardized instrument (eg, the American Urological Association [AUA] Symptom Scoring Index; Table 52–1). However, it is important to recognize that a patient’s perception of the bothersomeness of his voiding symptoms may not match with the AUA Symptom Score. In this case, after thorough evaluation of the signs and complications of BPH disease, if present, the physician and patient should discuss the bothersomeness of the patient’s symptoms and decide together on the most appropriate course of treatment for the patient.1,2 Lower urinary tract symptoms (LUTS) is a term that refers to the collection of obstructive and irritative voiding symptoms characteristic of, but not specific for, BPH. That is, other urologic diseases (eg, urinary tract infection, prostate cancer, prostatitis, or neurogenic bladder) can also cause LUTS.

Signs
- Enlarged prostate on digital rectal examination (DRE); check for prostate nodules or induration, which would suggest prostate cancer instead of BPH as the cause of the patient’s voiding symptoms
- Distended urinary bladder
- Rule out meatal stenosis or urethral stricture, which could cause voiding symptoms similar to LUTS
- Check anal sphincter tone as an indirect assessment of peripheral innervation to the detrusor muscle of the bladder

Complications of Untreated BPH
Upper and lower urinary tract infection, urosepsis, urinary incontinence refractory urinary retention, chronic renal failure, bladder diverticula, bladder stones, or recurrent gross hematuria.

Medical History
- Check the patient’s general health, including previous surgery, presence of diabetes mellitus, or medications that may cause or worsen voiding symptoms.
- Have the patient provide a diary of his voiding pattern for the past week: date and time of each voiding, volume voided, and whether or not the patient had urinary leakage during the day.

Laboratory Tests
- Serum PSA: The combination of PSA and DRE of the prostate can be used to screen for prostate cancer, which could also cause an enlarged prostate. Also, PSA is a surrogate marker for an enlarged prostate due to BPH. A PSA greater than 1.5 ng/mL (1.5 mcg/L) suggests that a patient has a prostate volume greater than 30 cm³ (30 g or 1.05 oz).7
- Urinalysis to rule out infection as a cause of the patient’s voiding symptoms; also check urinalysis for microscopic hematuria, which typically accompanies BPH.
- Plasma blood urea nitrogen (BUN) and serum creatinine may be increased as a result of long-standing bladder outlet obstruction. These tests are not routinely performed but rather are reserved for those patients in whom renal dysfunction is suspected.

Other Diagnostic Tests (Table 52–2)
- Decreased peak and mean urinary flow rate (less than 10–15 mL/s) on uroflowmetry; decreased urinary flow rate is not specific for BPH; it can also be due to other urologic disorders (eg, urethral stricture, meatal stenosis, or bladder hypotonicity).
- Increased postvoid residual urine volume (PVR) (greater than 50 mL)
- DRE to check for an enlarged prostate (greater than 15–20 g [0.5–0.7 oz]).
- A focused neurological examination to check the integrity of innervation to the urinary bladder (that is responsible for bladder emptying).
- Transurethral cystoscopy reveals an enlarged prostate, which decreases urethral lumen caliber; information from this procedure helps the surgeon decide on the best surgical approach.
- Transrectal ultrasound of the prostate; a transrectal probe is inserted to evaluate prostate size and best surgical approach.
- Transrectal prostate needle biopsy to be done if the patient has areas of nodularity or induration on DRE; tissue biopsy can document the presence of prostate cancer, which can also cause enlargement of the prostate.
- IV pyelogram (IVP) will show retention of radiocontrast in the bladder if the patient has bladder outlet obstruction due to an enlarged prostate; this is only indicated in patients with recurrent hematuria, recurrent urinary tract infection, renal insufficiency, and urolithiasis.
- Filling cystometry provides information on bladder capacity, detrusor contractility, and the presence of uninhibited bladder contractions, which could also cause LUTS.
FIGURE 52–1. Algorithm for selection of treatment for BPH based on symptom severity and presence of disease complications.

Table 52–1

Questions to Determine the AUA Symptom Score

Directions for the patient: The patient should be asked to respond to each question based on the absence or presence of symptoms over the past month. For each question, the patient can respond using a 1–5 scale, where 0 = not at all or none; 1 = less than 1 time in 5; 2 = less than half of the time; 3 = about half of the time; 4 = more than half of the time; and 5 = almost always.

Directions for the clinician: After the patient completes the questionnaire, the scores for individual items should be tallied for a final score. Scores of 0–7 = mild symptoms; scores of 8–19 = moderate symptoms; scores more than 20 = severe symptoms.

Questions to Assess Obstructive Voiding Symptoms
1. How often have you had a sensation of not emptying your bladder completely after you finished urinating?
2. How often have you found you stopped and started again several times when you urinated?
3. How often have you had a weak urinary stream?
4. How often have you had to push or strain to begin urinating?

Questions to Assess Irritative Voiding Symptoms
5. How often have you found it difficult to postpone urination?
6. How often have you had to urinate again < 2 hours after you finished urinating?
7. How many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?

KEY CONCEPT For patients with moderate to severe symptoms and no complications of BPH, the patient is usually offered drug treatment first. α-Adrenergic antagonists are preferred over 5α-reductase inhibitors because the former have a faster onset of action (days to a few weeks) and improve symptoms independent of prostate size. α-Adrenergic antagonists are preferred for patients with lower urinary tract voiding symptoms, who also have small prostates (less than 30 cm³ [approximately 30 g or 1.05 oz]).

5α-Reductase inhibitors have a delayed onset of action (ie, peak effect may be delayed for up to 6 months) and are most effective in patients with moderate LUTS and larger size prostate glands (greater than 30 g or 1.05 oz). Drug treatment must be continued as long as the patient responds (Table 52–5).7,14

Combination of medications to treat moderate or severe symptoms of BPH are more expensive and can cause more adverse effects than single drug treatment. Therefore, combination medication regimens are reserved for patients who have specific symptoms that do not respond to an adequate trial of single drug treatment or patients who are at high risk of developing complications of BPH. Refer to the section on Combination Therapy for a detailed description of various regimens and their advantages and disadvantages.

KEY CONCEPT For patients who are at risk of disease progression (ie, those with large prostates [greater than 30 g or 1.05 oz]), have moderate-severe symptoms that are not responsive to drug treatment, or have complications of BPH disease, surgery is indicated.7 Although it is potentially curative, surgery can result in significant morbidity, including erectile dysfunction, retrograde ejaculation, urethral stricture, urinary incontinence, bleeding, or urinary tract infection. The gold standard is prostatectomy, which can be performed transurethrally using electrocautery or...
Testosterone acts like a diuretic.

≥ 20

PVR > 50 mL is a significant amount of normal test result.

Midstream urine is analyzed microscopically for white blood cells and bacteria.

Urine should have no white cells or bacteria in it.

Urine with white blood cells and bacteria is suggestive of inflammation and infection; if positive, urine is sent for bacteriologic culture. The biopsy is consistent with BPH.

A normal prostate should have no evidence of BPH or prostate cancer.

A PSA > 1.5 ng/mL (1.5 mcg/L) is a surrogate marker for an enlarged prostate > 30 g (1.05 oz).

As an open surgical procedure, which can be performed supra- or retropubically. A transurethral prostatectomy is typically reserved for prostates of intermediate size (30 g [1.05 oz] to 80 g [2.83 oz]), whereas an open prostatectomy is used for very large prostates (greater than 80 g [2.83 oz]) or when the patient has BPH and other associated urologic disorders, for example, large bladder stones or bladder diverticula, that can be surgically treated at the same time. The newer bipolar technique for performing a TURP, which uses saline irrigating solution, has reduced the incidence of dilutional hyponatremia, a common adverse effect of the older monopolar technique, which uses glycine or sterile water irrigating solution. The outcomes of prostatectomy include an almost immediate improvement of LUTS, an increase of peak urinary flow rate by 6 to 15 mL/s, and a PVR decrease of 30 to 80 mL.

To minimize complications of prostatectomy or in patients who are taking anticoagulants, minimally invasive surgical procedures, such as transurethral incision of the prostate, transurethral needle ablation, transurethral microwave thermotherapy or transurethral laser ablation, are options. A

AUA, American Urological Association; BPH, benign prostatic hyperplasia; DRE, digital rectal examination; PVR, postvoid residual urine volume.

The AUA Symptom Score focuses on seven items (incomplete emptying, frequency, intermittency, urgency, weak stream, straining, and nocturia) and asks that the patient quantify the severity of each complaint on a scale of 0 to 5. Thus the score can range from 0 to 35. A decrease in score of 3 points or more is considered a clinically significant improvement.

A variety of ablative laser energy sources are used to vaporize tissue: holmium, potassium-titanyl-phosphate (KTP or green light), or diode. The choice of energy source is largely determined by the surgeon’s level of training, the patient’s anatomy, and potential risks for the patient. The potential advantages of minimally invasive surgical procedures include less blood loss, shorter periods of catheterization postoperatively, and the ability to complete the procedure on an outpatient basis. However, minimally invasive surgical procedures are associated with a higher reoperation rate than a prostatectomy. Drug treatment is used in patients with severe disease when the patient refuses surgery or when the patient is not a surgical candidate because of concomitant diseases.

### Nonpharmacologic Therapy (Behavioral Modification)

To reduce nocturia, patients should be instructed to stop drinking fluids 3 or 4 hours before going to bed and then void before going to sleep. During the day, timed voidings every 2 to 3 hours and use of double voiding help to empty urine from the bladder. Patients should avoid excessive caffeine and alcohol intake, because these may cause urinary frequency. Patients should avoid taking nonprescription medications that can worsen obstructive voiding symptoms (eg, antihistamines or decongestants) (see Table 52–4). In addition, toilet mapping (knowing the location of toilets on the way to and from various destinations) may help reassure the patient that he can still continue with many of his routine daily activities despite having LUTS. Patients are also advised to lose weight, if overweight. Because testosterone is converted to estrogen in adipose tissue, an alteration in the testosterone:estrogen ratio occurs in overweight men, similar to that which occurs in elderly males, which may contribute to the development of BPH.

Although a variety of herbal agents are used for symptomatic management, including pygeum (African plum), secale cereale (rye pollen), serenoa repens, and hypoxis rooperi (South African star grass), objective evidence of efficacy is lacking.

### Pharmacologic Therapy

#### α-Adrenergic Antagonist Monotherapy

- **α-Adrenergic antagonists reduce the dynamic factor causing BPH symptoms.** These drugs competitively antagonize α-adrenergic receptors, thereby causing relaxation of the bladder neck, prostatic urethra, and prostate smooth muscle. A secondary mechanism of action may be that α-adrenergic antagonists induce prostatic apoptosis, which suggests that these agents may cause some shrinkage of an enlarged prostate.

All α-adrenergic antagonists are considered equally effective in relieving symptoms. In various clinical trials, 30% to 80% of patients experience improvement in AUA Symptom Score by 30% to 45%, and 20% to 40% of patients experience urinary flow rate increases of 2 to 3 mL/s. The onset of action is...

+, minimal; ++ moderate.
days to weeks, depending on the need for titration of the dose from a subtherapeutic starting dose to a therapeutic maintenance dose. An adequate clinical trial is considered to be at least 1 to 2 weeks of continuous treatment at a full maintenance dose with any of these agents.1 Durable responses have been demonstrated for up to 10 years with doxazosin.19 However, some patients will develop disease progression despite treatment. α-Adrenergic antagonists are hepatically metabolized. Therefore, in patients with significant hepatic dysfunction, these drugs should be used in the lowest possible dose. With the exception of silodosin, these drugs do not require dosage modification in patients with renal dysfunction. These agents can be differentiated by their adverse effect profile. The most common dose-limiting adverse effects are hypotension and syncope, which are more common with immediate-release terazosin and doxazosin, less frequent with extended-release doxazosin and alfuzosin, and least frequent with pharmacologically uroselective α1A-adrenergic antagonists—tamsulosin and silodosin.20 Combined use with antihypertensives, diuretics, or phosphodiesterase type 5 inhibitors can lead to additive blood pressure–lowering effects; however, this appears to be less of a problem with tamsulosin and silodosin.21

α-Adrenergic antagonists can be distinguished by several characteristics:

- **Uroselectivity.** Pharmacologic uroselectivity refers to preferential inhibition of α1A receptors, which predominate in the prostatic stroma, prostate urethra, and bladder neck, and α1D receptors, which predominate in the bladder detrusor muscle.17 Pharmacologically uroselective α1A-adrenergic antagonists have the potential to produce less hypotension, because they have a lower propensity to antagonize α1B-adrenergic receptors in the peripheral vasculature. Tamsulosin and silodosin are the only commercially available α1A-adrenergic antagonists with pharmacologic uroselectivity.21 In contrast, despite the potential of inhibiting α-adrenergic receptors in both the prostate and peripheral vasculature, functionally uroselective α-adrenergic antagonists in usually prescribed doses produce effective relaxation of prostatic smooth muscle with minimal vascular vasodilation. Thus blood pressure–lowering effects are mild or absent. The only functionally uroselective α-adrenergic antagonist is alfuzosin extended-release tablets.22

**KEY CONCEPT** Both pharmacologically and functionally uroselective agents appear to be clinically uroselective, in that they improve BPH symptoms with a low potential to cause cardiovascular adverse effects in humans.17 They are preferred in patients who usually have low blood pressure or those taking multiple antihypertensives.20

Pharmacologic and functional uroselectivity are dose-related phenomena. Large daily doses of tamsulosin, silodosin, or alfuzosin may cause loss of uroselectivity, with resultant hypotension and dizziness in some patients.23 Despite the blood-pressure lowering property of α-adrenergic antagonists, they are not recommended to be used alone to treat patients with both BPH and essential hypertension. In the ALLHAT study24, where doxazosin was compared with other agents for treatment of essential hypertension, doxazosin was associated with a higher incidence of congestive heart failure. Therefore, in patients with both hypertension and moderate to severe LUTS, it is recommended that an appropriate antihypertensive be added to an α-adrenergic antagonist.

- **Need for up-titration of daily dose.** Up-titration is required for immediate-release terazosin and doxazosin. It is minimally required for extended-release doxazosin and tamsulosin. It is not required for extended-release alfuzosin or silodosin. The need for up-titration with a particular α-adrenergic antagonist delays its peak onset of action and the time when the patient can experience maximal clinical benefit.

- **Plasma half-life.** α-Adrenergic antagonists with short plasma half-lives (eg, prazosin) require multiple doses during the day. This is challenging for most patients, and thus prazosin is not recommended for BPH.7

- **Dosage formulation.** Immediate-release formulations of terazosin and doxazosin are quickly absorbed and produce high peak plasma levels. Modified- or extended-release formulations of doxazosin, alfuzosin, and tamsulosin produce lower peak levels, but more sustained therapeutic plasma levels, than immediate-release formulations and have less potential for producing hypotensive episodes. This allows for initiation of treatment with a therapeutic dose, a shorter time to peak onset of clinical effects, and once daily dosing.17

- **Adverse effects.** Hypotensive adverse effects of α-adrenergic antagonists can range from asymptomatic blood pressure reductions to dizziness and syncope. This adverse effect occurs in approximately 2% to 14% of treated patients and is most commonly associated with immediate-release terazosin and doxazosin; is less commonly associated with extended-release alfuzosin and extended-release doxazosin; and least commonly associated with tamsulosin and silodosin.21 To minimize first-dose syncope from terazosin and doxazosin immediate-release, a slow up-titration from a subtherapeutic dose of 1 mg/day to a therapeutic dose is essential. The first dose should be given at bedtime so that the patient can sleep through the peak serum concentration of the drug when the adverse effect is most likely to occur. A 3- to 7-day interval between each dosage increase should be allowed, and the patient should be maintained on the lowest effective dose of an α-adrenergic antagonist. If the patient is noncompliant with his regimen or he skips or interrupts treatment, the α-adrenergic antagonist should be restarted using the usual starting dose and then titrated up. He should not be instructed to simply double up on missed doses or resume treatment with his currently prescribed daily dose, as this can lead to significant hypotension or syncope.

Ejaculation disorders, including delayed, absent and retrograde ejaculation, occur with all adrenergic antagonists. This is largely thought to be due to pharmacologic blockade of peripheral α-adrenergic receptors at the bladder neck (ie, the bladder neck is unable to close during ejaculation in the presence of α-adrenergic blockade), however, a central nervous system mechanism of action cannot be discounted.25 The incidence appears to be dose-related and highest with daily doses of tamsulosin 0.8 mg and silodosin 8 mg, occurring in up to 26% and 28% of treated patients, respectively. Ejaculation disorders generally do not necessitate discontinuation of treatment, except in younger patients. Although this adverse effect may decrease the patient's satisfaction with the quality of sexual intercourse, ejaculation disorders are not harmful to the patient.

Rhinitis and malaise occur with α-adrenergic antagonists and are an extension of the pharmacologic blockade of α-adrenergic receptors in the vasculature of the nasal mucosa and in the central nervous system, respectively. Tolerance often develops to these adverse effects and they rarely require discontinuation of
treatment. Avoid use of topical or oral decongestants, as these may exacerbate obstructive voiding symptoms. Cautious use of antihistamines with anticholinergic adverse effects is also recommended in patients with severe BPH and large PVR’s, as these drugs may cause acute urinary retention in patients with an obstructed bladder neck.

Floppy iris or small pupil syndrome has been reported with α-adrenergic antagonists, most often with selective α₁a adrenergic antagonists.⁷,²⁶ In response to tamsulosin, the iris dilator muscle relaxes and the pupil constricts. As a result, when the α-adrenergic antagonist–treated patient undergoes cataract surgery, the iris can become flaccid, floppy, or billows out. This plus the pupillary constriction interfere with the surgical procedure and increase the risk of intraoperative and postoperative complications. A patient who plans to undergo cataract surgery is advised to inform his ophthalmologist that he is taking an α-adrenergic antagonist. Although the drug will not need to be held or discontinued, the ophthalmologist can plan to use certain surgical techniques, for example, iris hooks or iris expansion rings, to deal with the drug’s effect on the iris dilator muscle.⁷,²⁷,²⁸ Likewise, prior to initiating an α-adrenergic antagonist, a patient who needs cataract surgery should have this ophthalmologic procedure performed first, if possible.⁷

- **Potential for drug interactions.** Hypotensive adverse effects of terazosin and doxazosin can be additive with those of diuretics, antihypertensives, and phosphodiesterase type 5 inhibitors (eg, sildenafil). In patients at greatest risk for hypotension, or in those patients who tolerate hypotension poorly, including those with poorly controlled coronary artery disease or severe orthostatic hypotension, tamsulosin or silodosin appear to be the safest choice.²²,²⁶,²⁹ In patients who cannot tolerate any α-adrenergic antagonist, a 5α-reductase inhibitor or prostatectomy could be considered, particularly if the prostate is enlarged and greater than 30 g (1.05 oz). When initiating sildenafil, tadalafil, or vardenafil, α-adrenergic antagonists should be used cautiously as it undergoes extensive hepatic metabolism.

With regard to their use for the symptomatic treatment of BPH, finasteride and dutasteride are considered equally effective in relieving LUTS by 15% to 30% in 30% to 70% of patients and increasing the urinary flow rate by 1 to 2 mL/s, which is less improvement than that seen with α-adrenergic antagonists. A minimum of 6 months is required to evaluate the effectiveness of treatment. This is a disadvantage in patients with moderate to severe symptoms, as it will take that long to determine whether the drug is or is not effective. Durable responses have been demonstrated in responding patients treated up to 6 years with finasteride and 4 years with dutasteride. Unlike α-adrenergic antagonists, 5α-reductase inhibitors are used to prevent BPH-related complications and disease progression. Finasteride has been shown to reduce both the incidence of acute urinary retention by 57% and the need for prostate surgery by 55% in patients with significantly enlarged prostate glands (greater than 40 g [1.4 oz]). These agents are heptatically metabolized. No specific recommendations for dosage modification are currently available in patients with significant hepatic dysfunction; however, due to the drug’s specificity for its enzyme target, it is unlikely that any dosage adjustment will be required. No dosage adjustment is needed in patients with renal impairment. Adverse effects include decreased libido, erectile dysfunction, and ejaculation disorders, which may persist after the drug is stopped, and gynecomastia and breast tenderness. When used to prevent prostate cancer, these agents reduce the incidence of prostate cancer by 25%, but are suspected to increase the risk of developing moderate to high grade cancer, if prostate cancer does develop. Serum testosterone levels increase by 10% to 20% in treated patients; however, the clinical significance of this is not clear at this time. Drug interactions are uncommon. These drugs decrease serum levels of PSA by approximately 50%. Therefore, to preserve the usefulness of this laboratory test as a diagnostic and monitoring tool, it is recommended that prescribers obtain a baseline PSA prior to the start of treatment and repeat it at least annually during treatment. A significantly elevated PSA in treated patients suggests that the patient is not compliant with his prescribed 5α-reductase inhibitor regimen or is an indicator for further diagnostic workup for prostate cancer. Exposure to 5α-reductase inhibitors is contraindicated in pregnant females, as the drugs may cause feminization of a male fetus. Pregnant females should not handle these drugs unless they are wearing gloves.

**Combination Therapy**

A combination of an α-adrenergic antagonist and 5α-reductase inhibitor may be considered in symptomatic patients who do not respond to an adequate trial of monotherapy or in those at high risk of BPH complications, that is, those with an enlarged prostate of at least 30 g (1.05 oz). In such patients, combination therapy will relieve voiding symptoms and also may reduce the risk of developing BPH-related complications and reduce the need for prostatectomy by 67% after 4 years.

The Reduce Trial compared dutasteride, tamsulosin, and the combination of dutasteride and tamsulosin. Results showed that patients treated with the combination had greater symptom improvement after 9 months and less disease progression at 4 years than patients treated with single drug therapy. Because combination therapy is more expensive and associated with the array of adverse effects associated with each drug in the combination, clinicians should discuss the advantages and disadvantages of such a treatment regimen with the patient before a final decision is made (see Table 52-5). A commercially available combination formulation of dutasteride 0.5 mg and tamsulosin 0.4 mg may be convenient for some patients.

To streamline and reduce the cost of treatment regimens, it has been suggested that the α-adrenergic antagonist may be discontinued after the first 6 to 12 months of combination therapy in patients with moderate LUTS. However, in patients with severe LUTS and an enlarged prostate gland, the combination regimen should be continued as long as the patients are responding.

Another enhancement to BPH symptom management is the addition of an anticholinergic agent (eg, tolterodine) to an α-adrenergic antagonist with or without a 5α-reductase inhibitor. The rationale for the anticholinergic agent is that irritative symptoms (eg, urinary urgency and frequency) are thought to be due to hyperreactive bladder detrusor muscle contraction, which can be ameliorated by blockade of M1 and M3 muscarinic receptors. Also, α1a-receptor antagonists in the detrusor muscle, which cause muscle contraction when stimulated, can be blocked by α-adrenergic antagonists. An α-adrenergic antagonist may decrease involuntary bladder muscle contraction and increase the bladder’s compliance. Thus, the combination may have an additive pharmacologic effect on relieving irritative voiding symptoms. A recent meta-analysis documents the addition of an anticholinergic agent to an α-adrenergic antagonist produced significant irritative symptom improvement, more than what was observed with the α-adrenergic antagonist alone. No cases of urinary retention were reported. If irritative symptoms do not improve after starting an anticholinergic agent, up-titrating the dose or switching to another anticholinergic agent may be helpful. Patients at the highest risk of anticholinergic agent-induced acute urinary retention include those with a high postvoid residual urine volume (250 mL or more). Thus anticholinergic agents should be used cautiously in these patients. Finally, the medication profile of patients should be checked for overall anticholinergic burden, which increases the likelihood of anticholinergic adverse effects, including dry mouth, tachycardia, constipation, confusion, and drowsiness.

Once daily dosing of tadalafil is approved for treatment of LUTS. It may be prescribed alone, or along with an α-adrenergic antagonist or 5α-reductase inhibitor. Its mechanism may be due to relaxation of smooth muscle of the urethra, prostate, and bladder, which is mediated by inhibiting the Rhokininase pathway. This inhibits the proliferation and contraction of prostatic smooth muscle, or enhances the action of nitric oxide. Tadalafil is comparable to α-adrenergic antagonists in relieving LUTS and decreasing the AUA Symptom Score by 3.8 points after 12 weeks; however, it does not increase urinary flow rate or reduce PVR. Because tadalafil is expensive, the best candidates for treatment are those with BPH and erectile dysfunction.

---

**Patient Encounter 3**

A 66-year-old man with severe obstructive voiding symptoms of BPH presents to the clinic. A DRE reveals a prostate of 45 g (1.6 oz) and a PSA of 1.8 ng/mL (1.8 mcg/L). He is started on dutasteride 0.5 mg daily by mouth. After 3 months, the patient complains that his symptoms have not significantly improved.

**Explain why the patient has not responded to treatment.**

**Identify an alternative treatment regimen for this patient.**
dysfunction, or those patients with LUTS that is not responsive to α-adrenergic agonists. The usual recommended dose is 5 mg by mouth daily; the dose should be reduced to 2.5 mg daily if the creatinine clearance is 30 to 50 mL/min (0.50–0.83 mL/s). Tadalafil should be avoided if the creatinine clearance is less than 30 mL/min (0.50 mL/s). Tadalafil is contraindicated in patients on nitrates by any route of administration; patients with unstable angina, uncontrollable or high-risk arrhythmias, persistent hypotension, poorly controlled hypertension, or New York Heart Association Classification IV congestive heart failure; or patients who have had a myocardial infarction within the past 2 weeks. Common adverse effects include headache, dizziness, dyspepsia, back pain, and myalgia (Table 52–8).

Mirabegron is a β3-adrenergic agonist. When it stimulates beta3 adrenergic receptors in the urinary bladder detrusor muscle, mirabegron reduces irritative voiding symptoms and improves urine storage in the bladder. Although not FDA approved for this indication, mirabegron is an alternative to an anticholinergic agent in patients who poorly tolerate anticholinergic adverse effects or whose irritative voiding symptoms do not respond to an anticholinergic agent. Mirabegron is typically added to an α-adrenergic agonist. The usual dose is 50 mg by mouth daily; reduce the dose to 25 mg daily if the creatinine clearance is 15 to 29 mL/min (0.25–0.49 mL/s).

### Patient Encounter 4

A 67-year-old man presents with severe LUTS. His prostate gland is estimated to be 40 cm³ (40 g or 1.4 oz) in size and his PSA is 3 ng/mL (3 mcg/L). The patient also suffers from recurrent urinary tract infection and persistent gross hematuria. The patient’s peak urinary flow rate is 5 mL/s and PVR is 200 cm³ (200 mL). The patient’s AUA Symptom Score is 25. The patient prefers medical management for his BPH. He asks if tadalafil would be a good choice for him.

Is tadalafil a good choice? If not, what is the best treatment option for this patient?
Mirabegron should be avoided if the creatinine clearance is less than 15 mL/min (0.25 mL/s). Common adverse effects of mirabegron include headache, hypertension, tachycardia, constipation, and nasopharyngitis.

OUTCOME EVALUATION

**KEY CONCEPT** Once the peak effects of drug treatment are expected to occur, monitor the drug for effectiveness. This is approximately 1 month after the start of an α-adrenergic antagonist and 3 and 6 months after the start of a 5α-reductase inhibitor. Assess symptom improvement using the AUA Symptom Scoring Index. A reduction in symptom score by a minimum of 3 points is anticipated with symptom improvement. However, it should be noted that the AUA Symptom Score may not match the patient's perception of the bothersomeness of his voiding symptoms. If the patient perceives his symptoms as bothersome, independent of the AUA Symptom Score, consideration should be given to modifying the patient's treatment regimen. Similarly, a patient may regard his symptoms as not bothersome even though the AUA symptom score is high. In this case, the physician should objectively assess symptoms at baseline and during treatment by performing a repeat uroflowmetry, which can detect an improvement in peak and mean urinary flow rate, and checking for a reduction in PVR and the absence of complications of BPH. If the patient shows a response to treatment, instruct the patient to continue the drug regimen and have the patient return at 6-month intervals for monitoring. If the patient shows an inadequate response to treatment, the dose of α-adrenergic antagonist can be increased (except for extended-release alfuzosin and silodosin) until the patient's symptoms improve or until the patient experiences adverse drug effects.

For the α-adrenergic antagonists, the severity of hypotensive-related adverse effects, which may manifest as dizziness or syncope, may require a dosage reduction or a slower up-titration of immediate-release terazosin or doxazosin, or halting the up-titration of the α-adrenergic antagonist. If the patient develops adverse effects at this dose, the drug should be discontinued. Other adverse effects of α-adrenergic antagonists are nasal congestion, malaise, headache, and ejaculation disorders. None of

---

**The Patient Care Process**

**Patient Assessment:**
- Based on the patient's chief complaint and review of systems, determine whether the patient is experiencing LUTS.
- Review the medical history and physical examination. Does the patient have a history of BPH? Does he have an enlarged prostate? Does he have a history of complications of BPH, for example, recurrent urinary tract infection, gross hematuria, acute urinary retention, and so on. Have various tests been performed to establish the severity of BPH (Table 52–2)?
- Conduct a medication history (including prescription and over the counter medications, and dietary supplements) that could be contributing to his voiding symptoms (Table 52–4). Does the patient have any drug allergies? Is the patient receiving treatment for LUTS (Table 52–5)? If yes, when was the treatment started and has the patient completed an adequate clinical trial? Is the patient experiencing adverse effects from therapy (Table 52–8)?
- Review available laboratory tests, especially serum electrolytes, renal function, and urinalysis.
- Assess the severity of the patient's LUTS by having the patient complete the AUA Symptom Scoring Index (Table 52–3).

**Therapy Evaluation:**
- If the patient is already receiving medications for LUTS, assess the efficacy, safety, and patient adherence. Are there any significant drug interactions?
- If the patient needs to be started on drug therapy, ensure that the patient has moderate or severe LUTS, check prostate size, and check patient for any contraindications or precautions for various treatments. Is the patient at risk of BPH progression? Does the patient prefer medical or surgical treatment of BPH?
- Determine whether the patient has prescription coverage or whether recommended agents are included on the institution's formulary.

**Care Plan Development:**
- Institute nonpharmacologic therapies to minimize LUTS.
- Institute appropriate medication treatment for moderate or severe LUTS.
- Determine whether drug dose is optimal (Table 52–6 and 52–7).
- Address any patient concerns about LUTS, BPH, and management.
- Discuss importance of medication adherence and nonpharmacologic therapies to control LUTS.

**Follow-Up Evaluation:**
- After starting an α-adrenergic antagonist, assess effectiveness and safety of therapy in 1 month, and then at 6 months. At each visit, repeat AUA Symptoms Scoring Index, check for disease progression, repeat urinary flow rate and PVR and for adverse effects of treatment. As long as the patient continues to respond and tolerates the medication well, repeat all assessments at yearly intervals thereafter.
- After starting a 5α-reductase inhibitor, assess effectiveness and safety of therapy at the end of the third and sixth month. At each visit, repeat AUA Symptoms Scoring Index, check for disease progression, repeat urinary flow rate and PVR and for adverse effects of treatment. As long as the patient continues to respond and tolerates the medication well, repeat all assessments at yearly intervals thereafter.
these generally require discontinuation of treatment, and these often improve as treatment continues. For the 5α-reductase inhibitors, the most bothersome adverse effects are decreased libido, erectile dysfunction, and ejaculation disorders. In sexually active males, erectile dysfunction may be improved with erectogenic drugs; however, this adverse effect may necessitate discontinuation of treatment.

During continuing treatment of BPH, the patient should undergo an annual repeat PSA and DRE. A rising PSA level suggests that the patient has worsening BPH, new-onset prostate cancer, or that the patient is noncompliant with his regimen of 5α-reductase inhibitor. An abnormal DRE suggestive of prostate cancer would reveal a nodule or area of induration on the prostate. In such a case, a prostate biopsy is required to rule out prostate cancer.

Drug treatment failures may result from a variety of factors. Initial failure to respond to α-adrenergic antagonists occurs in 20% to 70% of treated patients. It is likely in these patients that the static factor may predominate as the cause of symptoms in these patients. In these patients, adding a 5α-reductase inhibitor may be helpful. Initial failure to respond to 5α-reductase inhibitors occurs in 30% to 70% of treated patients. It is likely that the dynamic factor may predominate as the cause of symptoms in these patients. In these patients, switching to or adding an α-adrenergic antagonist may be helpful. In contrast, drug treatment failures after an initial good response to drug therapy will likely be an indication of progressive BPH disease. In such patients, modifying the drug regimen or surgical intervention may be indicated.

Table 52–8 summarizes the adverse effects of the agents used to treat BPH and includes management suggestions for these situations.

### References

LeaRning ObJEctIves

Upon completion of the chapter, the reader will be able to:
1. Explain the pathophysiology of the major types of urinary incontinence (UI): urge, stress, overflow, and functional.
2. Recognize the signs and symptoms of the major types of UI in individual patients.
3. List the treatment goals for a patient with UI.
4. Compare and contrast available therapeutic agents for managing UI; identify factors that guide drug selection for an individual patient.
5. Formulate a monitoring plan and provide patient counseling for a patient on a given treatment regimen based on patient-specific information.
6. Explain the pathophysiology of pediatric enuresis.
7. List treatment goals; compare and contrast available therapeutic agents for managing pediatric enuresis.
8. Formulate a patient-specific monitoring plan and implement patient counseling for a patient on a given treatment regimen.
9. Describe nonpharmacologic treatment approaches for pediatric enuresis.

Urinary Incontinence and Pediatric Enuresis
Sum Lam

Urinary Incontinence

INTRODUCTION
Urinary incontinence (UI) is defined as the complaint of involuntary leakage of urine. It is often associated with other bothersome lower urinary tract symptoms such as urgency, increased daytime frequency, and nocturia. Despite its prevalence across the lifespan and in both sexes, it remains an underreported health problem that can negatively impact an individual’s quality of life. Patients with UI may sense a loss of self-control, independence and self-esteem, and often modify their activities for fear of an “accident.” Patients with UI may also suffer from other consequences, including perineal dermatitis and infections, pressure ulcers, urinary tract infections (UTIs) and falls. In the United States, the estimated national cost of urge urinary incontinence (UUI) in 2007 was $66 billion, with projected costs of $76 billion in 2015 and $83 billion in 2020.

Epidemiology and Etiology
The true prevalence of UI is unclear because of varying definitions of UI and reporting bias. About 44% of noninstitutionalized persons aged 65 and older reported UI. 7% to 37% of women aged 20 to 39 report some degree of UI. 9% to 39% of women age 60 and over report daily UI. 11 to 34% among older men report some degree of UI. 2 to 11% of older men reporting daily UI.
In the noninstitutionalized setting, more than 50% of elderly women and more than 25% of elderly men reported UI. 46% of short-term and 76% of long-term nursing home residents report UI.

UI can result from abnormalities within (intrinsic to) and outside of (extrinsic to) the urinary tract. Within the urinary tract, abnormalities may occur in the urethra (including the bladder outlet and urethral sphincters), the bladder, or a combination of both structures. Focusing on abnormalities in these two structures, a simple classification scheme emerges for all but the rarest intrinsic causes of UI. Accurate diagnosis and classification of UI type is critical to the selection of appropriate drug therapy.

Pathophysiology
Stress Urinary Incontinence
Stress urinary incontinence (SUI) occurs most frequently in women and is related to the underactivity of urethra and/or urethral sphincters, leading to inadequate resistance to impede urine flow from the bladder. SUI occurs when intra-abdominal pressure is elevated by exertional activities like exercise, running, lifting, coughing, and sneezing. SUI is usually episodic, associated with small volume leakage and rarely causes nocturia or enuresis. The etiology for urethral underactivity is not
A 62-year-old Asian woman presents to the clinic with the chief complaint of “not being able to make it to the toilet in time.” Every day she experiences a strong, sudden urge to urinate which is difficult to postpone. She makes about 10 trips to a bathroom while awake on a daily basis and gets up twice each night to urinate. She reports no clothes-wetting accidents so far, but is fearful of the embarrassment, especially when she is in the public. Because of the urinary condition, she has given up shopping in large malls, which was her favorite pastime. She also avoided several social and family events in the past month. She states that “life would be so much better if I don’t need to run for the bathroom.” She denies any urinary leakage when she coughs, laughs, or exercises. Her PVR is less than 10 mL. She is diagnosed with overactive bladder without urinary incontinence.

List symptoms that are consistent with her diagnosis.

What additional information do you need to know before creating a treatment plan for this patient?

completely understood, although the loss of the trophic effects of estrogen on the uroepithelium at menopause is thought to be important. The peak of SUI prevalence in the perimenopausal years supports this hypothesis. Clearly established risk factors for SUI include the following:

- Pregnancy (increased risk with increased parity)
- Childbirth (vaginal delivery)
- Menopause
- Cognitive impairment
- Obesity
- Increasing age

SUI is exceedingly rare in males unless the sphincter mechanism is compromised by surgery or trauma. The most common surgeries predisposing to SUI in males are radical prostatectomy for prostate cancer and transurethral resection of the prostate for benign prostatic hyperplasia (BPH).

Urge Urinary Incontinence

UUI is related to the overactivity of detrusor muscle in the bladder, which contracts inappropriately during the filling (urinary storage) phase and generates urgency, or a compelling desire to void which is difficult to defer. The bladder contractions are due to the stimulation of muscarinic cholinergic receptors, especially M2 and M3 subtypes. UUI is associated with large volume leak age, sometimes complete bladder emptying, nocturia and enuresis; thus UUI may disrupt sleep. Overactive bladder (OAB) is a symptom syndrome with or without associated UUI.

Most women with UUI or OAB have no identifiable causes (idiopathic), while in men similar symptoms are associated with benign prostatic hyperplasia (See Chapter 52). Overactivity may be myogenic and/or neurogenic. Clearly established risk factors for UUI include:

- Older age
- Neurologic disorders (eg, stroke, Parkinson disease, multiple sclerosis, and spinal cord injury)
- Bladder outlet obstruction (eg, benign or malignant prostatic enlargement or hyperplasia)

- Hysterectomy
- Recurrent UTIs

Overflow Urinary Incontinence

Overflow urinary incontinence (OUI) is a less common form of UI in men or women. It is related to urethral overactivity and/or bladder underactivity. In short, the bladder is filled to capacity at all times but cannot empty, causing urine to leak out episodically. If caused by bladder underactivity, the progressively weakened detrusor muscle eventually loses the ability to voluntarily contract, which lead to incomplete voiding and large residual urinary volume after micturition. Both myogenic and neurogenic factors have been associated with impaired bladder contractility that leads to OUI. Common neurogenic factors are diabetes, lower spinal cord injury, multiple sclerosis, or radical pelvic surgery.

If due to urethral overactivity, incomplete bladder emptying occurs because the resistance of the urethra and/or sphincters cannot be overcome by detrusor contractility. In men, this most frequently occurs in cases of long-term chronic bladder outlet obstruction due to BPH, prostate cancer, or abdominal-pelvic surgeries. In women, urethral overactivity is rare, but may result from cystocele formation or surgical overcorrection for SUI. In both genders, systemic neurologic diseases such as multiple sclerosis or spinal cord injury may be the etiology.

Functional UI

Functional UI is generally caused by extrinsic factors to the urinary tract, such as:

- Immobility (due to pain, physical limitations)
- Inadequate or delayed access to toileting facilities
- Neurologic impairment (Parkinson disease, multiple sclerosis, spinal cord injury, stroke, apathy due to depression)
- UTIs
- Postmenopausal atrophic urethritis and/or vaginitis
- Diabetes mellitus (glucosuria leading to polyuria)
- Diabetes insipidus (polyuria due to decreased antidiuretic hormone [ADH])

Clinical Presentation of Stress Urinary Incontinence (SUI) Related to Urethral Underactivity

General

Usually occurs during activities like exercise, running, lifting, coughing, or sneezing; much more common in females.

Symptoms

Urine leakage volume is proportional to activity level; not associated with nocturia. No SUI with physical inactivity, especially when supine. May develop urgency and frequency as a compensatory mechanism (or independently as a separate component of bladder overactivity).

Diagnostic Tests

Observation of urethral meatus (opening) while patient coughs or strains.
Clinical Presentation of Urgent Urinary Incontinence (UUI) Related to Bladder Overactivity

**General**
If sensory input from the lower urinary tract is absent, may have bladder overactivity and urine leakage without urgency. Patient with overactive bladder (OAB) may not have UUI.

**Symptoms**
Patients with OAB typically present with symptoms of urgency, frequency (8 or more micturitions in 24 hours), nocturia (one or more awakenings per night to void) with or without UUI.

**Diagnostic Tests**
Urodynamic studies are the gold standard for diagnosis. Urinary tract infection must be ruled out by urinalysis and urine culture.

---

Clinical Presentation of Overflow Urinary Incontinence (OUI) Related to Urethral Overactivity and/or Bladder Underactivity

**General**
Rare type of UI in both genders. Urethral overactivity is usually due to prostatic enlargement (males) or cystocele formation or surgical overcorrection for SUI (females). Bladder underactivity is usually due to a weakened detrusor muscle.

**Symptoms**
Lower abdominal fullness, hesitancy, straining to void, decreased force of stream, interrupted stream, sense of incomplete bladder emptying. May have urinary frequency and urgency, as well as abdominal pain if acute urinary retention occurs.

**Signs**
Increased postvoid residual urine volume.

---

Mixed and Drug-Induced UI
Mixed urinary incontinence (MUI) occurs when two or more types of UI coexist in a given patient, which may lead to diagnostic and therapeutic difficulties. Patients may experience worsening of symptom due to the opposing effects of treatments indicated for specific and different types of UI.

**KEY CONCEPT** Many medications can influence the lower urinary tract system, and can precipitate or aggravate existing voiding dysfunction that leads to UI (Table 53–1).

examination to check rectal tone, reflexes, ability to perform a voluntary pelvic muscle contraction in females; size and surface quality of prostate in males)

- Pelvic examination in women for evidence of prolapse of bladder, small bowel, rectum, or uterus, or signs of estrogen deficiency
- Genital/prostate exam in men
- Urinalysis, PVR urine volume
- Direct observation of urethral meatus (opening) when patient coughs/strains (urine spurt consistent with SUI) (cough stress test)
- Perineal examination for skin maceration, redness, breakdown, ulceration, and evidence of fungal skin infection
- Optional: voiding diary, assessment of incontinence severity (Table 53–3), quality-of-life measures

**TREATMENT**

Desired and realistic treatment outcomes should be individualized and discussed with each patient. The treatment goals for UI may change with time, often requires reaching a compromise between efficacy and tolerability of drug therapy.

**Desired Outcomes**

- Restoration of continence
- Reduction of the number of UI episodes (daytime and nighttime) and nocturia
- Prevention or delaying of complications associated with UI (eg, pressure ulcers, skin conditions)
- Minimization of adverse effects and costs related to treatment
- Improvement in quality of life

**Nonpharmacologic Treatment**

At the primary care level, nonsurgical, nonpharmacologic intervention constitutes the chief approach to the management of UI. It has no adverse reactions, is minimally invasive, and can be utilized adjunctively with other treatment modalities. Nonpharmacologic treatment gives at least an additive effect in efficacy when combined with drug therapy, and can allow the use of lower drug doses. It is ideal for patients who fit the following scenarios:

- Medically unfit for surgery
- Planning for pregnancies/childbirths, which can compromise the long-term results of certain types of continence surgery

Sum of OABSS scores _____

The sampling period is usually defined as “the past week” but, depending on the usage, it can be amended to, for example, “the past 3 days” or “the past month.” Whatever the case, it is necessary to specify the sampling period.

Diagnostic criteria for OAB are “an urgency score for Question 3 of 2 or greater, and an OABSS of 3 or greater.” OABSS may also be used for assessing the severity of OAB: a total score of 5 or less (mild), 6 to 11 (moderate), and 12 or more (severe).

- Having OUI whose condition is not amenable to surgical or drug treatment
- Avoiding drug therapy or surgery due to safety concern or patient preference

These approaches include lifestyle/behavioral modifications, fluid management, scheduled voiding regimens, pelvic floor muscle rehabilitation (PFMR), external neuromodulation, anti-incontinence devices, acupuncture, and supportive interventions. Many of these are best utilized through attendance at multidisciplinary UI clinics staffed by specialized healthcare providers. Of note, weight loss of 5% to 10% in overweight or obese women has an efficacy similar to that of other nonpharmacologic treatments for treating SUI.

Bladder training and prompted voiding improves symptoms of UUI and MUI. PFMR is an effective treatment for adult women with SUI and MUI. Combination therapy with PFMR plus behavioral training achieved better outcomes than drug therapy in women with UUI. Also, this combination treatment was the only nonpharmacologic treatment that renders true objective evidence of restoring continence. However, these methods require motivation from patients. Medical conditions, such as cognitive dysfunction, may interfere with active participation and compromise efficacy. Regular follow-up is important for monitoring outcomes and for providing reassurance and support. Lifestyle/behavioral interventions should be continued during drug therapy in patients with UI, even if the results have not fully achieved the desired outcomes.

External neuromodulation may include nonimplantable electrical stimulation, percutaneous tibial nerve stimulation, or extracorporeal magnetic stimulation. This treatment option is typically prescribed when traditional PFMR has failed. Anti-incontinence devices, such as bed alarms, catheters, pessaries, penile clamps, and external collection devices, are reserved for special situations depending on patient’s symptoms, cognition, mobility status, and overall health status. Supportive interventions such as physical therapy may be beneficial for patients with muscle weakness and slow gait that hinder their reach to the toilet in a timely manner. Last, absorbent products provide greater patient confidence in dealing with unpredictable urine loss.

Surgery is rarely an initial treatment for UI; only considered in patients with significantly bothersome symptoms, and when nonsurgical options are undesired or ineffective. Surgery is not as helpful for bladder underactivity but can be used to manage urethral overactivity due to BPH and bladder outlet obstruction (via endoscopic incision using a cystoscope). It is most effective for SUI by stabilizing the urethra and bladder neck and/or augmenting urethral resistance. Common approaches are injection of periurethral bulking agents and midurethral sling procedure. In males, SUI is best treated by implanting an artificial urinary sphincter.
Office based injection of botulinum toxin A directly into the smooth or striated muscle. The injections are performed in the office generally with local anesthesia. The duration of effect of the toxin is about 4 to 8 months after which repeat injection is necessary to maintain effect. Intravesical (bladder) botulinum toxin A injections increased bladder capacity/compliance and improved quality of life in patients with refractory OAB.

Patients with UUI and an elevated PVR urine volume may require intermittent self-catheterization along with frequent voiding between catheterizations. Surgical placement of a supra-pubic catheter may be necessary in cases when intermittent catheterization is not possible. Catheterization can be combined with pharmacologic treatment for symptom relief.

**Pharmacologic Treatment**

The ideal treatment agent must have clinical efficacy, minimal side effects, minimal drug–drug/drug–disease interactions, convenient administration, and low cost. Patient characteristics (eg, age, comorbidities, concurrent drug therapies, and ability to adhere to the prescribed regimen) can influence drug therapy selection. Although a recent systematic review has shed light on the comparative data on newer agents, extended-release (ER) agents (oxybutynin XL, tolterodine LA, trospium ER, darifenacin ER, fesoterodine ER) cause less dry mouth, constipation, headache, dyspepsia, dry eyes, cognitive impairment, tachycardia, and urinary retention (Table 53–4). Older patients are especially susceptible to these adverse events. Significant dry mouth can be associated with dental caries, ill-fitting dentures, and swallowing difficulty. Chewing sugarless gum or use of saliva substitutes can help to alleviate dry mouth.

Orthostatic hypotension and sedation can be particularly troublesome to patients with cognitive impairment or at risk for falls. Issues with tolerability and multiple daily dose administration associated with IR products may jeopardize medication adherence and can prevent dose titration to achieve optimal clinical response. Thus, these IR products are not preferred in patients with functional limitations and/or those who are already taking complicated drug regimens. Nevertheless, adverse events are not universal and the severity varies with individuals. Older agents, when initiated at the lowest possible doses and gradually titrated, are reasonable to consider in patients where a long-acting product is undesirable.

Extended-release (ER) agents (oxybutynin XL, tolterodine LA, trospium ER, darifenacin ER, fesoterodine ER) cause less dry mouth compared with IR products. These products cannot be chewed, crushed, or divided, and must be swallowed whole. Oxybutynin transdermal patch and topical gel are alternatives for patients who cannot take or tolerate oral drugs; they have lower rates of dry mouth but are associated with application site

**Patient Encounter 1, Part 3: Creating a Care Plan**

Patient prefers to try a drug that is least likely to cause dry mouth. She is willing to try topical agents.

Based on the information presented, create a care plan for this patient’s OAB. Your plan should include:

1. A statement of the drug-related needs and/or problems
2. The goals of therapy
3. A patient-specific detailed therapeutic plan, including patient counseling to enhance medication adherence, ensure successful therapy, and minimize adverse effects
4. A plan for follow-up to evaluate therapeutic outcome and drug tolerability

---

Reactions. Rotation of application sites can be helpful to minimize the side effects.

Patients receiving any antimuscarinic agent should be informed about sedation as a possible side effect and warned against operating heavy machinery, such as driving, especially during the initial phase of therapy. Patients with existing cognitive dysfunction or difficulty with balance should be monitored closely for mental status changes and risk for falls. Older individuals are more prone to have constipation of age-related physiologic changes and the increased likelihood of receiving other medications that may exacerbate constipation. Patients should be advised to contact their physician if they experience severe abdominal pain or become constipated for 3 or more days. An important drug–drug interaction to avoid is the concurrent use of acetylcholinesterase inhibitors, which are used to treat dementia (antagonism) and any other anticholinergic agents (increase side effects).

**Antimuscarinic agents should be initiated at the lowest possible dose and gradually titrated upward based on clinical response; not to exceed the maximum recommended doses.** A trial of at least 4 weeks is required to evaluate its efficacy. Consider switching to another agent if the patient reports intolerable side effects or inadequate symptom relief despite optimized dose.

**Mirabegron** Mirabegron is a β₃-adrenergic agonist approved in June 2012 for the treatment of OAB with UUI. Like antimuscarinic agents, it reduces urinary frequency and incontinence episodes by less than one per day and is also considered the first-line drug therapy for OAB (see Table 53–4). It increases bladder capacity by relaxing the detrusor smooth muscle during the storage phase of the urinary bladder fill-void cycle. It requires 4 to 8 weeks of therapy for optimal efficacy.

Mirabegron is available in ER tablets, and should be swallowed whole without chewing, dividing, or crushing. Most commonly reported adverse reactions were hypertension (7%–11%), nasopharyngitis (4%), urinary tract infection (3%–6%) and headache (3%–4%). Patient should be monitored for increased blood pressure and urinary retention, particularly in patients with bladder outlet obstruction or those who are taking anticholinergic drugs.

Currently, there is no direct comparison of mirabegron and antimuscarinics for efficacy or tolerability.

**Older Agents** Tricyclic antidepressants (TCA), such as desipramine, nortriptyline, imipramine, and doxepin, are generally no more effective than oxybutynin IR. They may cause potentially serious adverse effects (eg, orthostatic hypotension, cardiac conduction abnormalities, dizziness, and confusion); thus should be limited to individuals who have one or more indicated comorbidities (eg, depression or neuropathic pain); patients with MUI (because of their effect of decreasing bladder contractility and increasing outlet resistance); and possibly those with nocturnal incontinence associated with altered sleep patterns. Propacetamine, flavoxate, dicyclomine, and hyoscyamine are not recommended due to lack of efficacy and/or significant adverse effects.

**Stress Urinary Incontinence**

The goal of pharmacologic therapy of urethral underactivity is to improve the urethral closure mechanism:

- Stimulating α-adrenoceptors in the smooth muscle of the proximal urethra and bladder neck
- Enhancing the supportive structures underlying the urethral mucosa
- Enhancing the positive effects of serotonin and norepinephrine in the afferent and efferent pathways of the micturition reflex

*All values constitute mean data, predominantly using product information from the manufacturers.*
In generally, there is no role for pharmacologic therapy in SUI in men resulting from surgery or trauma. Initial data, however, suggest a possible role for duloxetine added to PFMR in males status postradical prostatectomy, at least over the first 4 to 6 months. Unlike UUI, SUI in women is frequently curable by surgery, thus obviating years of drug therapy that may not provide adequate symptom relief. Surgery (tension-free vaginal tape sling) is a more cost-effective therapy of SUI than duloxetine in women failing PFMR.

**Estrogens**

Vaginally administered estrogen plays a limited role in managing SUI unless local signs of estrogen deficiency (eg, atrophic urethritis or vaginitis) are present. Estrogen products are believed to work by a trophic effect on uroepithelial cells and underlying collagenous subcutaneous tissue, enhancement of local microcirculation by increasing the number of periurethral blood vessels, and enhancement of the number and/or sensitivity of α-adrenoceptors.

Since 1940s, estrogens administered by various routes (oral, transdermal, and local) have been used to manage SUI although recent trials showed them to be no better than placebo. Actually, oral hormone replacement therapy increases the risk of new-onset UI (SUI, UUI, MUI) while carrying numerous short- and long-term risks, including mastodynia (pain in the breast), uterine bleeding, nausea, thromboembolism, cardiac/cerebrovascular ischemic events, and breast/endometrial cancer. In contrast, local estrogens (estradiol [not available in the US] tablets, conjugated equine estrogen cream, estradiol rings, pessaries) have demonstrated subjective improvement in SUI and UI in general. Thus, clinicians may consider only locally administered estrogen products for SUI while monitor for individual response (Table 53–6).

**α-Adrenoceptor Agonists**

Phenylpropanolamine, ephedrine and pseudoephedrine have been used alone or with estrogen for mild and moderate SUI. However, recent data showed that they are not better than placebo or PFMR. Phenylpropanolamine has been removed from the market in the United States due to associated risk of ischemic stroke. However, clinicians should be aware that it can still be purchased via the Internet and should discourage its use. Ephedrine, although still available by prescription, should not be used for SUI due to toxicity and lack of efficacy data. The major impediment to using α-adrenoceptor agonists is the extensive list of contraindications (see Table 53–6). Side effects of pseudoephedrine, an over-the-counter drug, include hypertension, headache, dry mouth, nausea, insomnia, and restlessness.

**Duloxetine**

This selective serotonin-norepinephrine reuptake inhibitor can be used for SUI in the United States. It enhances central serotonergic and adrenergic tone, which is involved in ascending and descending control of urethral smooth muscle and the internal urinary sphincter, and thereby enhances urethral and urinary sphincter smooth muscle tone during the filling phase. Recent review shows that it slightly improved incontinence, and may give greater benefit when combined with PFMT. Preliminary results suggest that it may also benefit incontinence and quality of life in men with SUI after radical prostatectomy.

The use of duloxetine in SUI is complicated by intolerability (eg, high rates of nausea), numerous precautions or contraindications, cytochrome P450 (CYP) drug–drug interactions, and possibility of withdrawal symptoms if abruptly discontinued. Duloxetine discontinuation rate at 1 year is as high as 66%, with two-thirds of discontinuations related to adverse events and one-third for lack of efficacy. The most common adverse events reported with duloxetine for SUI were nausea (up to 46%), headache (up to 27%), constipation (up to 27%), dry mouth (up to 22%), and insomnia (up to 14%). Overall, adherence to long-term duloxetine therapy is poor due to adverse events and lack of efficacy.

The usual dosage is 40 to 80 mg/day (in one or two doses) for 12 weeks. Gradual dose titration (starting from 20 mg once daily for at least 1 week, then titrate no shorter than weekly interval) may help to reduce the risks of nausea, dizziness, and premature therapy cessation. Similarly, taper the dose to avoid withdrawal symptoms if duloxetine is discontinued. Dose reduction of 50% for 2 weeks before discontinuation or slow tapering over 4 to 6 months is reasonable. If intolerable withdrawal symptoms occur following a dose reduction, consider resuming the previously prescribed dose and/or decrease dose at a more gradual rate.

### Overflow Incontinence

There is no established effective pharmacologic therapy for OUI due to bladder underactivity (atonic bladder). A trial of bethanechol (25–50 mg three or four times daily) may be reasonable if contraindications do not exist. Bethanechol is a cholinomimetic that has uncertain efficacy but is associated with bothersome and potentially life-threatening side effects (muscle and abdominal cramping, hypersalivation, diarrhea, and bronchospasm), particularly in patients with preexisting conditions. α-Adrenoceptor antagonists, such as silodosin, prazosin, terazosin, doxazosin, tamsulosin, and alfuzosin, may be beneficial for OUI by relaxing the bladder outflow tract and hence reducing outflow resistance. If pharmacologic therapy fails, intermittent urethral catheterization by the patient or caregiver three or four times per day is recommended. Less satisfactory alternatives include indwelling urethral or suprapubic catheters or urinary diversion. In OUI due to obstruction, such as BPH, the goal of treatment is to relieve the obstruction.

### Mixed Urinary Incontinence

MUI is usually a combination of UUI plus SUI with one dominant component. It accounts for one-third of UI cases in women. A reasonable management approach is a combination of lifestyle/behavioral modifications and PFMR with pharmacotherapy appropriate to the dominant type of UI. For instance, antimuscarinics can be offered in UUI-predominant cases, whereas duloxetine, local estrogen, and α-adrenoceptor agonists in SUI-predominant cases. In some cases, the less dominant form of UI may respond, but usually not to a degree that is considered adequate by the patient. Most experts feel that SUI-predominant MUI is best treated initially using the nonpharmacologic approach plus surgery for SUI. Unfortunately, these patients with MUI are expected to have a lower success rates with surgery compared to those with pure SUI. The urge component may get better, stay the same, or get worse after surgery. Unfortunately, there is no a priori way to predict the response in a given individual.

### OUTCOME EVALUATION

- Monitor the patient for symptom relief. Have the treatment achieved the desired outcomes jointly developed by the health care team and the patient/caregiver? If so, to what
degree? Inspect the daily diary completed by the patient/caregiver and quantitate the clinical response (eg, number of micturitions, number of incontinence episodes, and pad use) since the last visit. If a diary has not been used, ask the patient how many incontinence pads have been used and how they have been doing in terms of “accidents” since the last visit. If appropriate, administer a short-form instrument to measure the impact of symptoms, including quality of life. Compare the findings with previous results.

- Ask patients about adverse effects of drug therapy using a nonleading approach. Ask the patient/caregiver to judge their severity and what measures, if any, they have used to alleviate. Assess medication adherence (ask patient/caregiver about missed doses or do a pill count if the prescription containers are available at the visit).
- The balance of clinical response and tolerability should guide whether the drug dosage is increased, decreased, or left unchanged. Consider stopping/tapering off the regimen and initiate another drug option if bothersome adverse effects compromise patient safety and/or medication adherence.

INTRODUCTION

Urinary incontinence is a common problem in children, and treatment is unnecessary in children younger than 5 years, in whom spontaneous cure is likely. Pediatric enuresis (also called “intermittent nocturnal incontinence” or “nocturnal enuresis”) is a condition, which can present alone or coexist with other disorders in children and adolescents. It is defined as discrete episodes of UI during sleep in children at least 5 years old. Common terms associated with enuresis are as follows:

- Monosymptomatic enuresis: Enuresis in children without any other lower urinary tract symptoms and without a history of bladder dysfunction
- Primary enuresis: A process wherein the patient has never been consistently dry throughout the night
- Secondary enuresis: A process wherein the patient has resumed wetting after a period of dryness of at least 6 months in duration
- Nonmonosymptomatic enuresis: Enuresis in children with other lower urinary tract symptoms (eg, urgency, frequency, daytime incontinence, genital or lower urinary tract pain)

Enuresis is not a benign disorder that children will just “grow out of.” The emotional and developmental damage produced by enuresis may be more significant to the child than the enuresis itself. Emotional and/or physical abuse of the child by adult caregivers can lead to secondary problems such as chronic anxiety, low self-esteem, and delayed developmental milestones (attending camp, “sleepovers” at the homes of friends, etc).

EPIDEMIOLOGY AND ETIOLOGY

Five to seven million children and adolescents in the United States suffer from nocturnal enuresis. With each year of maturity, the percentage of bed-wetters declines by 15%. Primary enuresis is twice as common as secondary enuresis, which is present in 15% to 25% of bed-wetters. In the enuretic population, 80% to 85% are monosymptomatic, 5% to 10% are nonmonosymptomatic, and less than 5% have an organic cause. Every year about 15% of those suffering from primary monosymptomatic nocturnal enuresis have spontaneous resolution without treatment. The prevalence of enuresis is as follows:

- At age 5: 15% to 25%
- At age 12: 8% (boys) and 4% (girls)
- Adolescents: 1% to 3%

The etiology of enuresis is poorly understood, but there is a clear genetic link. Loci for enuresis have been located on chromosomes 5, 12, 13, and 22. The incidence in children from families with both parents had enuresis as children reaches as high as 77%, compared to 44% in whom from families with one parent had enuresis as a child, and 14% in whom from families with no members with enuresis. Sleep disorders are not considered major contributors, with the exception of sleep apnea. Enuresis occurs in all sleep stages in proportion to the time spent in each stage. However, a small proportion of individuals are not aroused from sleep by bladder distention and have uninhibited bladder contractions preceding enuresis.
PATHOPHYSIOLOGY

There are potentially treatable organic causes of enuresis (Table 53–7). Vast majority of children with enuresis have normal urodynamics, including functional bladder capacity, or maximum voided volume. Expected bladder capacity can be estimated by this formula: (30 + [30 × age]) mL.

In some children, there appears to be a relationship between developmental immaturity in motor and language milestones and enuresis, but the mechanism is unknown. There is evidence that affected individuals have an attenuated vasopressin circadian rhythm (more significant in girls) with lower vasopressin plasma concentrations. Other contributors include detrusor over-activity at night, increased threshold for arousal, and taking certain drugs (eg, lithium, clozapine, risperidone, valproic acid, selective serotonin reuptake inhibitors, and theophylline). Interestingly, caffeine ingestion does not correlate with enuresis. In a minority of cases, psychological factors (eg, divorce of parents, school trauma, sexual abuse, or hospitalization) are clearly contributory to secondary enuresis. In very rare cases, severely dysfunctional families may neglect to properly toilet train the children.

TREATMENT

Desired Outcomes

- Reduction in the number of enuresis episodes and restoration of continence

UTI, urinary tract infection.

- Partial response: a 50% to 89% decrease
- Response: 90% or more decrease
- Full response: a 100% decrease or less than 1 symptom occurrence monthly
- Prevention of relapse (greater than 1 symptom recurrence monthly) and maintenance of treatment success
- Continued success: No relapse in 6 months after the interruption of treatment
- Complete success: No relapse in 2 years after the interruption of treatment
- Prevention or minimization of disease complications (delay in childhood developmental milestones, adverse psychological effects on the child/caregivers)
- Minimization of adverse effects and costs related to treatment
- Improvement in the quality of life of the child and caregivers

**Clinical Presentation and Diagnosis: Pediatric Enuresis**

Proper assessment of the child or adolescent with enuresis should explore every aspect of UI, especially the genitourinary and nervous systems. The minimum assessment should include:

- Interview of child and parent(s), being sensitive to the emotional consequences of the enuresis.
- Direct physical examination, looking for enlarged adenoids/tonsils, bladder distention, fecal impaction, abnormal genitalia, spinal cord anomalies, and abnormal neurologic signs (look for an organic cause amenable to surgery or drugs; see Table 53–7).
- Obtain urinalysis for glucose, protein, WBC, or leukocyte esterase; obtain urinalysis and urine culture if symptoms of UTI are present.
- A 7 or more day diary of wet and dry nights prior to intervention is useful to monitor the response to treatment.
- Nonmonosymptomatic enuresis may require a more elaborate workup, including voiding cystourethrogram, renal and/or bladder ultrasound, urodynamics, and sleep studies.

- Partial response: a 50% to 89% decrease
- Response: 90% or more decrease
- Full response: a 100% decrease or less than 1 symptom occurrence monthly
- Prevention of relapse (greater than 1 symptom recurrence monthly) and maintenance of treatment success
- Continued success: No relapse in 6 months after the interruption of treatment
- Complete success: No relapse in 2 years after the interruption of treatment
- Prevention or minimization of disease complications (delay in childhood developmental milestones, adverse psychological effects on the child/caregivers)
- Minimization of adverse effects and costs related to treatment
- Improvement in the quality of life of the child and caregivers

**General Approach to Treatment**

Treatment is guided by the findings of the patient assessment. A referral to urologists is needed in cases of daytime wetting, abnormal voiding (eg, unusual posturing, discomfort, straining, poor stream), history of recurrent UTIs, and abnormalities of the genitalia. Crisis intervention strategies and individual and/or family psychotherapy are recommended in the rare circumstance of a true psychological cause.

Guidelines for the evaluation and management of nocturnal enuresis have been developed. Management of primary monosymptomatic nocturnal enuresis in children may involve one or a combination of interventions. The management of secondary nocturnal enuresis focuses on addressing the underlying stressor. However, most children with secondary enuresis have...
no identifiable causes and are treated in the same manner. The algorithm within the NICE guideline (Figure 53–1) is inclusive of the most potentially useful treatments and distinguishes approaches based on the child’s age, maturity, and abilities; the frequency of enuresis; and the motivation and needs of the family.39

Initial management with education and motivational/behavioral therapy (Table 53–8) should be utilized for 3 to 6 months, provided that the patient and family are sufficiently motivated.35 More active intervention (eg, enuresis alarm, pharmacologic treatment) is warranted if initial management fails or provides inadequate response. KEY CONCEPT Enuresis alarms are the most effective long-term therapy, but desmopressin is effective in the short-term (eg, for sleepovers or camp attendance). KEY CONCEPT Pharmacotherapy is most valuable in patients who have difficulty in adhering to nonpharmacologic therapy or in those who fail to achieve desired outcomes with nonpharmacologic therapy.

► Nonpharmacologic Treatment

The standard first-line therapy demands for commitment from the child and/or caregiver (see Table 53–8). It involves education about the condition, fluid/diet modification, journal keeping, and behavioral or motivational therapy.35,40 Motivational therapy allows about 25% of children to achieve 14 consecutive dry nights and 70% of them at least a partial response. About 5% of children experience more than 2 wet nights in 2 weeks. If motivational therapy fails to lead to improvement after 3 to 6 months, active interventions, such as enuresis alarms (Table 53–9) or desmopressin, may be added.36

Enuresis alarms are indicated for motivated families and children with frequent enuresis of more than twice per week. They conditioned the child to learn to wake or inhibit bladder contraction in response to the physiologic conditions present before wetting. They are the most effective ways of controlling nocturnal enuresis and preventing relapse, and may be used in children younger than 7 years. They are more effective than TCAs for pediatric enuresis.41 Alarm therapy can be an effective add-on in patients who are partial- or nonresponders to drug therapy alone. Similarly, drug therapy can be added in patients who achieved suboptimal results from nonpharmacologic therapy alone.42,43

Use of enuresis alarms does not provide rapid or short-term improvement, and requires the child be able to wake to sound or touch. Approximately 30% of patients discontinue enuresis alarms for various reasons, including skin irritation, disturbance of other family members, and/or failure to wake the child.35 Adverse effects of alarms include alarm failure, false alarms, failure to wake the child, disruption of other family members, and lack of adherence because of difficulty using the alarm.41 Efficacy may be assessed within 1 to 2 weeks of initiating alarm therapy. Treatment should be continued if the child demonstrates early signs of response. It often requires 3 to 6 months to achieve a minimum of 14 consecutive dry nights. After 3 months of therapy, if the child has achieved at least some response, alarm therapy should be continued.35,36 If no improvement is seen in 3 months, alternative interventions should be considered. However, enuresis alarm can be reinitiated for relapses.36 Measures that do not help or are of questionable value in pediatric enuresis include the following:44

• Bladder stretching exercises (done by delaying voiding despite the urge to do so)
• Hypnotherapy
• Dietary changes
• Desensitization to allergens
• Acupuncture
• Chiropractic

► Pharmacologic Treatment

Desmopressin (DDAVP)35,48 A synthetic analogue of vasopressin, desmopressin was first studied in enuresis in the 1970s. It is indicated for nocturnal enuresis in children at least 6 years of age who do not respond to initial management (see Table 53–8), or as an alternative for alarm therapy. It is most effective in children with nocturnal polyuria (nocturnal urine production greater than 130% of expected bladder capacity for age) and normal functional bladder capacity (maximum voided volume greater than 70% of expected bladder capacity for age). It decreases the number of wet nights per week by about one night. About 30% of children become full responders while on the drug, but 60% to 70% of them experience relapses.35 Desmopressin is the drug of choice in pediatric enuresis. In many countries the enuresis indication has been removed or desmopressin was first studied in enuresis in the 1970s. It is indicated for nocturnal enuresis in children at least 6 years of age who do not respond to initial management (see Table 53–8), or as an alternative for alarm therapy. It is most effective in children with nocturnal polyuria (nocturnal urine production greater than 130% of expected bladder capacity for age) and normal functional bladder capacity (maximum voided volume greater than 70% of expected bladder capacity for age). It decreases the number of wet nights per week by about one night. About 30% of children become full responders while on the drug, but 60% to 70% of them experience relapses.35 Desmopressin is the drug of choice in pediatric enuresis. In many countries the enuresis indication has been removed for nasal desmopressin due to higher risk for hyponatremic seizure. Oral desmopressin is an ideal agent for rapid-onset, short-term use (camp attendance or “sleepovers”). To aim for long-term benefit, consider a trial for at least 3 to 6 months. Regular tablets may be started at 0.2 mg (one tablet) 1 hour
Table 53–8

Initial Management of Pediatric Enuresis

Education and Advice to Children and Caregivers

- Enuresis is common; it occurs at least once per week in up to 25% of 5 year olds; enuresis resolves on its own in the majority of children.
- Enuresis is the fault of neither the child nor the caregivers; children should not be punished for bedwetting.
- Reduce the impact of bedwetting by using bed protection and washable/disposable products; using room deodorizers; thoroughly washing the child before dressing; and using emollients to prevent chafing.
- Keeping a calendar of wet and dry nights helps to determine the effect of interventions.
- The child should attempt to void regularly during the day and just before going to bed (a total of four to seven times); if the child wakes at night, the caregivers should take him/her to the toilet.
- Avoid high-sugar and caffeine-based drinks, particularly in the evening hours.
- Concentrate daily fluid intake in the morning and early afternoon. Restrict fluid and solute intake during the evening. A recommendation is to drink 40% of their total daily fluid intake between 7 AM and 12 PM, 40% in the afternoon between 12 PM and 5 PM, and only 20% in the evening after 5 PM.
- Discourage routine use of diapers and pull-ups, except when the child is sleeping away from home.

Motivational Therapy

- Motivational therapy is a good first-line therapy for nocturnal enuresis in younger children between the ages of 5 to 7 years who do not wet the bed every night.
- Motivate the child by keeping a record of progress and receive rewards for accomplished agreed-upon behavior, such as going to the toilet before bedtime. For example, a sticker on a calendar for each dry night, a book for seven consecutive dry nights, etc. Do not use penalties (ie, removal of previously gained rewards).

This begins with an intensive first night of training that involves increased fluid consumption, hourly awakenings, and a minimum of 2 weeks of alarm use. The caregiver fully awakens the child shortly before he or she would usually have wet the bed; once the child is consistently dry, the frequency of awakening drops or (for single awakenings) the time of awakening is gradually moved to earlier in the night (ie, closer to bedtime) until the child is dry when awakened 1 hour after going to bed. An alarm device and a moisture-sensitive sensor are used in combination, with the sensor being placed under the sheets, or more commonly, attached to the child’s pajamas or underwear near the urethra. The arousal devise is usually an auditory alarm and/or a vibrating belt or pager.

Table 53–9  
Behavioral Treatments for Enuresis

<table>
<thead>
<tr>
<th>Treatment</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Lifting</td>
<td>Procedure wherein the caregiver takes the child to the toilet at regular intervals during the night to urinate without fully awakening him or her.</td>
</tr>
<tr>
<td>Night awakening</td>
<td>Procedure wherein the caregiver fully awakens the child to void shortly before he or she would usually have wet the bed; once the child is consistently dry, the frequency of awakening drops or (for single awakenings) the time of awakening is gradually moved to earlier in the night (ie, closer to bedtime) until the child is dry when awakened 1 hour after going to bed.</td>
</tr>
<tr>
<td>Alarm</td>
<td>An alarm device and a moisture-sensitive sensor are used in combination, with the sensor being placed under the sheets, or more commonly, attached to the child’s pajamas or underwear near the urethra. The arousal devise is usually an auditory alarm and/or a vibrating belt or pager.</td>
</tr>
<tr>
<td>Overlearning</td>
<td>This is commenced at a minimum of 2 weeks after the alarm has rendered the child dry; the child drinks 500 mL (about 16 oz) during the hour before going to bed; alarm use is continued until he or she is dry for a maximum of 240 mcg.</td>
</tr>
<tr>
<td>Dry-bed training</td>
<td>This begins with an intensive first night of training that involves increased fluid consumption, hourly awakenings, praise when the bed is dry at hourly awakenings, and, when the alarm goes off, a mild reprimand and cleanliness training (child changes wet clothes and bed linens, remakes the bed, resets the alarm); before going to bed and after each wetting, the child engages in 20 practice trials of appropriate toileting (ie, positive practice); for each practice trial, the child lies in bed, counts to 50, arises and attempts to urinate in the toilet, then returns to bed; on subsequent nights, child is woken only once, usually about 3 hours after the child has gone to bed; after a dry night, the night awakening moves up 30 minutes earlier; it is discontinued when it is scheduled to occur 1 hour after bedtime; after 7 consecutive dry nights, the alarm is discontinued, but is reinstated if two episodes of wetting occur in a 1-week period.</td>
</tr>
</tbody>
</table>

The most serious complication of desmopressin therapy is water intoxication with dilutional hyponatremia and seizures. This occurs most frequently with the nasal formulation. Electrolyte monitoring in patients taking the oral formulation is recommended if comorbidities may exacerbate renal or electrolyte complications. To reduce the risk of water intoxication, children should drink no more than 8 oz (240 mL) of fluid from 1 hour before to 8 hours after administration of desmopressin. Treatment should be interrupted during episodes of fluid intake and/or electrolyte imbalance (eg, fever, recurrent vomiting or diarrhea, vigorous exercise, or other conditions associated with increased water consumption). 35

Treatment response should be assessed within 1 to 2 weeks. If signs of response are present, desmopressin should be continued for 3 months. If enuresis improves or remits, the family and child can determine whether to use desmopressin every night or just for special occasions, such as sleepovers. When it is administered daily, desmopressin should be withheld for 1 week every 3 months to determine whether continued use is necessary. 35

Lack of response to desmopressin may be due to reduced nocturnal bladder capacity (the most common reason for unresponsiveness) or persistent nocturnal polyuria (related to increased fluid intake in the evening, increased nocturnal solute excretion) or suboptimal dosing. To minimize relapses, daily desmopressin should be tapered over at least 2 weeks using one-half of the effective doses or giving the effective dose every other day for 2 weeks before discontinuation. 35

Diuretics play a minor role in the treatment of enuresis for most patients. However, in cases of presumed desmopressin resistance that leads to poor response to usual doses or symptom deterioration after established positive response, oral furosemide 0.5 mg/kg in the early morning may be helpful. Furosemide works by reversing the abnormal circadian rhythm of renal tubular sodium handling, which is common in individuals with enuresis. In a study with 12 children with desmopressin-resistant enuresis, adding furosemide appeared beneficial in 75% of study subjects. 46

Imipramine 47 Imipramine was first used in the treatment of enuresis in the 1960s. It is considered as the third-line option for monosymptomatic enuresis and may be used in children who have failed alarm therapy and desmopressin. Its mechanism of action is unclear but anticholinergic and antispasmodic effects may increase plasma ADH concentrations. About 50% of patients may respond to treatment and can expect approximately one less wet night per week. Although trials involving other TCAs have been performed over the years, there is insufficient evidence to assess their relative efficacy compared with imipramine.

Treatment with imipramine is associated with a reduction of approximately 1 wet night per week and relapse rates after cessation as high as 50%. The usual initial dose is 10 to 25 mg at bedtime and may be increased by 25 mg if there is no response after 1 week. On average, the bedtime dose is 25 mg for children 5 to 8 years of age and 50 mg for older children. The dose should not exceed 50 mg in children between 6 and 12 years of age and 75 mg in children age 12 or older. 35

About 25% of children treated with TCAs experience gastrointestinal symptoms. About 5% of children experience neurologic side effects including nervousness, personality change, or sleep disturbances. Clinicians should monitor for the possibility of increased suicidality, particularly in children and young adults with preexisting depressive symptoms. 33 The most serious adverse effects of TCAs are cardiac conduction disturbances and myocardial depression, particularly in cases of overdose. Therefore, safer options should be considered before starting any TCA for pediatric enuresis. 33,35
Anticholinergics  Monotherapy with anticholinergic drugs is ineffective in treating monosymptomatic nocturnal enuresis. These agents should be used only if the child has nocturnal enuresis and daytime incontinence (see Urinary Incontinence). In this case, anticholinergic therapy may be used in combination with desmopressin to increase bladder capacity during sleep. 35  

The usual initial dose of oxybutynin is 5 mg, tolterodine 2 mg, or 0.4 mg/kg propiverine (not available in the United States) at bedtime, titrate upward based on clinical response; the maximal therapeutic effects can be seen within 2 months or sometimes much earlier. 33  

Children should be monitored for major adverse events, such as urinary retention (may lead to urinary tract infections), constipation (worsens urinary tract dysfunction) and decreased saliva secretion.  

Other Drugs  Various medications, such as indomethacin, phenmetrazine, amphetamine sulfate, atropine, furosemide, diclofenac, and chlorprothixene have been tried in the treatment of nocturnal enuresis. Data suggest that indomethacin, diclofenac, and diazepam are superior to placebo, but not better than desmopressin. 47  

Current guidelines do not recommend any of these agents for pediatric enuresis.  

► Comparison of Therapies  

Multiple meta-analyses have been conducted to compare treatments for enuresis, although most trials enrolled a small number of subjects and were of poor methodological quality. 45,47–49  

Overall, data suggest that use of enuresis alarms is the most effective nonpharmacologic method. The initial rate for success (less than 1 wet night per month) is 66%, with 45% long-term success rate after discontinuation (vs 1% with no treatment). Alarm therapy is at least as effective as desmopressin, but with a significantly lower relapse rates (46% vs 60%–70% for desmopressin). 35  

Combining enuresis alarms and other behavioral therapy further reduces relapse rates. There is inadequate data to compare the various commercial brands of alarms available to consumers.  

► Treatment of Relapse  

A relapse is defined by more than 1 wet night per month after a period of dryness. 32  

When it occurs, reinitiate the intervention which was previously effective (see Figure 53–1). For children with multiple recurrences after discontinuation of desmopressin, gradual dose tapering of desmopressin may be helpful. Combination alarm and desmopressin therapy may be beneficial for children who have more than one recurrence following successful treatment with an alarm. 45  

Management of therapy-resistant monosymptomatic nocturnal enuresis may include periodic new trials of the enuresis alarm with or without desmopressin, desmopressin alone, or a trial of imipramine. 35  

Nonresponders experience less than 50% improvement in symptoms despite active interventions. 32  

When motivated children and families do not respond to at least 3-month therapy of enuresis alarm and/or desmopressin, referral to a specialty clinic (eg, developmental-behavioral pediatrician, pediatric urologist) may be warranted. 45  

OUTCOME EVALUATION  

• Monitor the patient for symptom relief. Has the treatment plan achieved the desired outcomes jointly developed by the health care team, the patient, and parents/guardians? If so, to what degree? Evaluate the daily diary completed by the patient or parents/guardians since the last clinic visit and  

Patient Care Process: Pediatric Enuresis  

Patient Assessment:  

• Assess the patient’s symptoms. Determine whether the child should be referred to a specialty clinic. Assess whether there are any exacerbating factors or enuresis related complications.  

• Review past medical history and available diagnostic data. Are there any potentially treatable organic causes of enuresis (see Table 53–7)?  

• Obtain a thorough medication history, including use of prescription, nonprescription, and complementary/alternative drug products. Could any of them contributing to enuresis (see Table 53–1)? Determine which, if any, treatments in the past had been helpful.  

• Establish realistic treatment goals with the involvement of the child and caregiver.  

Therapy Evaluation:  

• If patient is already receiving nonpharmacological interventions and/or drug therapy, assess treatment choice, drug dosing, efficacy, side effect, adherence, etc.  

• Have the child and caregiver given the current treatment plan an adequate duration of trial? How is the child responding to current treatment plan?  

Care Plan Development:  

• Educate the patient and/or caregiver on pediatric enuresis, lifestyle modifications, and motivational therapy (see Table 53–8). The patient and/or caregiver should be referred to local enuresis clinics (if available) for training in behavioral treatments, such as use of enuresis alarms (see Table 53–9). May follow treatment algorithms from current guidelines (see Figure 53–1).  

• Evaluate the patient for adverse events, allergies, and interactions (drug–drug and drug–disease) and adherence.  

• Provide the patient and/or caregiver with education regarding drug therapy (timing of drug administration, side effects, potential drug–drug interactions, etc).  

Follow-Up Evaluation:  

• Evaluate treatment response in 1 to 2 weeks after therapy initiation.  

• Allow at least 3 months to assess efficacy of treatment.
quantitate the clinical response (the number of dry nights per week, the number of nights with two or more enuresis episodes). If a diary has not been used, eliciting from the patient and caregiver the clinical response since last visit.

- Elicit adverse events of therapy, including severity, using a nonleading manner. Ask the patient or parents/guardians what measures, if any, were used to alleviate adverse effects. Assess therapy adherence.
- The balance of clinical response, tolerability, and burden on the caregiver will determine the approach to management. As most nonpharmacologic approaches are “all or none” and drug titration is limited by the maximum recommended dose, clinicians may consider changing therapy if clinical results are inadequate over an adequate trial period.
- Refer patients with refractory enuresis to a health care professional who specializes in the management of bedwetting.

ACKNOWLEDGMENT
The author and editors wish to acknowledge and thank Dr. David Guay, the primary author of this chapter in the first, second and third editions of this book.

Abbreviations Introduced in This Chapter

ADH  
Antidiuretic hormone

BPH  
Benign prostatic hyperplasia

Urge urinary incontinence

REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the potential incidence of allergic and pseudoallergic reactions and why it is difficult to obtain accurate numbers.
2. Describe the Gell and Coombs categories of reactions.
3. Identify the classes of drugs most commonly associated with allergic and pseudoallergic reactions.
4. Recommend specific treatment for a patient experiencing anaphylaxis.
6. Describe drug desensitization procedures for selected drugs.

INTRODUCTION

Allergic and pseudoallergic drug reactions are reported together. They are rarely confirmed by testing, making statistical analysis imprecise, with both over-reporting and under-reporting. Approximately 5% to 10% of adverse drug reactions are allergic or immunologic; however, allergic and pseudoallergic reactions represent 24% of reported adverse drug reactions in hospitalized patients. These reactions are costly and cause considerable morbidity and mortality. Between 10% and 20% of hospitalized patients incur drug reactions (7% in the general population), with about one-third possibly due to hypersensitivity; however, most of these reactions are not reported, especially in pediatrics. Patients experiencing an allergic drug reaction in the hospital have increased costs of $275 to $600 million annually. This financial burden can occur due to several reasons, including increased indirect cost of (a) time and lost labor; (b) use of more costly alternative medications; and (c) treatment failures. Outpatient rates are not well studied and are much harder to collect. Relying on a patient’s history without an attempt to verify the relationships between drugs taken and symptoms experienced results in confusion. Health care professionals and patients use the term “drug allergy” in such a general way that it is not medically useful and, further, perpetuates a level of fear and concern in the public and in medical practice that is inappropriate and costly. This same confusion and anxiety sometimes lead medical personnel to ignore or forget “drug allergy” with potentially catastrophic results. Clearly, an understanding of how allergic and pseudoallergic reactions occur and how they might be managed or prevented is important to health care professionals and their patients.

PATHOPHYSIOLOGY

Drug allergies are immune responses resulting from different mechanisms of immunologic recognition and activation, and reactions are produced by multiple physiologic pathways. This produces a confusing spectrum of clinical pictures and complex pathophysiologic mechanisms. The Gell and Coombs classification has been used for decades and still provides a framework for thinking about mechanisms of immunologic drug reactions, as shown in Table 54–1. However, as knowledge has advanced, the immune mechanisms active in most drug reactions have been found to be more complex and interrelated than suggested by the Gell and Coombs classification. The complexity and unpredictability of most immune-mediated drug reactions combined with the lack of appropriate animal models have hindered a better understanding of the mechanisms of these reactions. However, even with these shortcomings, the classification remains the most commonly used method for attempting to describe drug reactions resulting from hypersensitivity.

Immediate or Type I reactions are those allergic reactions mediated by IgE antibodies specific to the drug. Type II reactions are cytotoxic reactions mediated by drug-specific IgG or IgM antibodies; Type III reactions result from immune complexes circulating in the serum; and Type IV reactions are mediated by cellular mechanisms. Type IV reactions are further subdivided into Type IVa involving recruitment of monocytes, Type IVb with predominately eosinophils, Type IVc composed of CD4+ or CD8+ T cells, and Type IVd showing neutrophils.

Immune Mechanisms

The immune mechanisms involved in drug allergies are quite complex. Immune recognition of non-self material is predominantly controlled by specific receptors on the surface of T-cells during interactions with cells specialized for presenting antigens to T-cells. The antigen presenting cells must concomitantly provide a second signal in addition to the antigen to activate the T-cell. If a second signal is not provided, the T-cell becomes nonresponsive or anergic. The second signal controls the type of immune response that will be initiated by the T-cell.
Depending on the exposure to antigens and the cytokines involved, naïve T-helper cells (CD4+ T cells) can differentiate into at least five types of effector-helper cells: Type 1 effector helper T cells (Th1), Th2, Th17, Th9, and Th22. Each of these subsets of T cells appears to have a unique regulatory element, pattern of cytokine production, and function. Th1 responses are typically associated with activation of T-cells to induce B-cell immunoglobulin G (IgG) antibody production and to provide direct T-cell recruitment of cells to kill cells infected with viruses or intracellular bacteria. Th2 immune responses typically lead to IgE production and immediate allergic-type reactions. Th17 responses are varied but usually highly inflammatory and important in the clearance of extracellular bacterial and fungal infections. Th17 cells have also been found to be involved in a variety of autoimmune disorders such as psoriasis, rheumatoid arthritis, and inflammatory bowel disease. Th9 cells promote tissue inflammation and cause mucous production but do not have suppressor functions. Th22 cells produce abundant quantities of interleukin 22 (IL-22) and are important in various inflammatory diseases of the skin.

**Antigens**

The immune system normally is not capable of recognizing small molecules. This fact has resulted in several hypotheses concerning how drugs can elicit an immune response. The first widely accepted hypothesis was the **haptenation** hypothesis. This hypothesis states that the drug becomes covalently bound to a normal “self” protein and the combination of the drug bound to the protein is large enough to be recognized as foreign by the immune system, leading to an immune response. Another hypothesis is the pharmacologic interaction (p-i) hypothesis which states that the drug (or metabolite) directly binds to the T-cell receptor, initiating an immune response. In this case, T-cells are directly activated, despite not interacting with antigen presenting cells.

As suggested by several of these hypotheses, the metabolism of the drug often plays a critical role. The fact that many drugs are primarily metabolized in the liver helps to explain why the liver is often involved in adverse drug reactions. It has also been recognized that skin keratinocytes are a site of drug metabolism. This discovery helps explain why the skin is involved in many forms of reactions elicited by different drugs. Indeed some of the most common of the life-threatening drug reactions are predominately cutaneous, including Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and drug reaction with eosinophilia and systemic symptoms (DRESS) or drug-induced hypersensitivity syndrome (DIHS).

**Pseudoallergic Drug Reactions**

Reactions that clinically resemble allergic reactions but lack an immune basis are referred to as “pseudoallergic.” They include almost the entire range of immediate hypersensitivity clinical patterns. Pseudoallergic reactions range in significance from the alarming but trivial anxiety or vasovagal reactions caused by local dental anesthetics to sometimes fatal reactions to ionic radiocontrast media.

Pseudoallergic reactions are important in patient counseling and management considerations. They represent common biological functions such as direct histamine [H] release by vancomycin or opiates, whereas immunologic (allergic) reactions are based on the structure of the drug. Even a mild drug allergy may carry significant potential for anaphylaxis on readministration. In contrast, pseudoallergic reactions tend to remain constant whether mild or severe and are dose related.

Pseudoallergic reactions, then, are reactions where the components of the immune system are used in exactly the same way, but without the “learning” response by T cells and generally without the much greater danger that true immunologic sensitization implies. Pseudoallergic reactions may be thought of as a subtype

*These drugs represent a list of causative agents. Many drugs can cause these reactions.

†IVb and IVc reactions may combine to produce erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Ig, Immunoglobulin.
Clinical Presentation and Diagnosis of Allergic and Pseudoallergic Drug Reactions

The clinical presentation of a patient experiencing an allergic reaction varies greatly. The primary reactions are as follows:

**Anaphylaxis**
Anaphylaxis is an acute life-threatening allergic reaction. Signs and symptoms involve the skin (eg, pruritus, urticaria), respiratory tract (eg, dyspnea, wheezing), gastrointestinal tract (eg, nausea, cramping), and cardiovascular system (eg, hypotension, tachycardia). Onset is usually within 30 minutes, but can be as long as 2 hours. Treatment must begin immediately. Anaphylaxis may recur 6 to 8 hours after exposure, so patients should be observed for at least 12 hours.

**Cytotoxic Reactions**
These reactions usually take the form of hemolytic anemia, thrombocytopenia, granulocytopenia, or agranulocytosis.

**Immune Complex Reactions**
These reactions usually involve a serum sickness-like syndrome (eg, arthralgias, fever, malaise, and urticaria) that typically develops 7 to 14 days after exposure to the causative antigen.

**Dermatologic Reactions**
Rashes may range from mild to life-threatening.
- **Urticaria**: These are itchy, raised, swollen areas on the skin. Also known as hives.
- **Maculopapular rash**: A rash that contains both macules and papules. A macule is a flat, discolored area of the skin, and a papule is a small raised bump. A maculopapular rash is usually a large area that is red and has small bumps.
- **Erythema multiforme**: A rash characterized by papular (small raised bump) or vesicular lesions (blisters) and reddening or discoloration of the skin, often in concentric zones about the lesion.
- **Stevens-Johnson syndrome**: A severe expression of erythema multiforme (also known as erythema multiforme major). It typically involves the skin and the mucous membranes, with the potential for severe morbidity and even death.
- **Toxic epidermal necrolysis**: A life-threatening skin disorder characterized by blistering and peeling of the top layer of skin.

Anaphylaxis is a true medical emergency and must be treated promptly. Otherwise, managing allergic reactions begins with stopping the offending agent. Understanding the allergic reaction and potential for cross-allergenicity between similar drugs will assist in selecting an alternative medication. Desensitization is a management option if the patient truly needs the medication and alternative drugs are not available. Although any drug may cause an allergic or pseudoallergic reaction, several drugs and drug classes are strongly associated with such reactions (Table 54–2). These classes will be discussed individually.

**β-Lactam Antibiotics**
Hypersensitivity reactions with β-lactam antibiotics, especially penicillin, may encompass any of the Types I through IV Gell-Coombs classifications. The most common reactions are maculopapular and urticarial eruptions. Although rare (less than 0.05%), anaphylactic reactions to penicillins cause the greatest concern, because they are responsible for the majority of all drug-induced anaphylaxis deaths in patients, accounting for 75% of all anaphylaxis cases in the United States. The treatment of anaphylaxis is given in Table 54–3.

The health care professional is faced with a difficult task when approaching a patient who claims a history of penicillin allergy. Although as many as 12% of hospital patients state they have an allergy to penicillin, about 90% will have negative skin tests. This test only evaluates IgE-mediated reactions. A patient with a history of other serious reactions such as erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis should not receive penicillins and should not be tested.

**Penicillins and cephalosporins** both have a β-lactam ring joined to an S-containing ring structure (penicillins: a thiazolidine ring; cephalosporins: a dihydrothiazine ring). The extent of cross-allergenicity appears to be relatively low, with an estimate of approximately 4%. Cross-allergenicity is less likely with newer
generation cephalosporins compared with the first-generation agents. Anaphylactic reactions to cephalosporins are rare, with a predicted range of 0.0001% to 0.1%. Minor skin reactions including urticaria, exanthems, and pruritus are the most common allergic reactions with cephalosporins, showing severe reactions less often than with penicillins.19

For other β-lactam agents, the recommendations are fairly straightforward. Carbapenems should be considered potentially cross-reactive with penicillins and used with caution.20 Monobactams (eg, aztreonam) do not cross-react with any β-lactam drugs except ceftazidime because they share an identical R-group side chain.

### Table 54–2

**Problematic Drug Classes**

- β-Lactam antibiotics
- Sulfonamide antibiotics
- Aspirin and nonsteroidal anti-inflammatory drugs
- Radiograph media
- Opiates
- Cancer chemotherapy
- Insulin
- Anticonvulsants

### Table 54–3

**Pharmacologic Management of Anaphylactic Reactions**

#### Immediate Intervention

**Epinephrine 1:1000 (1 mg/mL)**
- Adults: Give 0.2–0.5 mg IM; repeat every 5 minutes as needed
- Pediatrics: 0.01 mg/kg (maximum 0.3 mg) IM; repeat every 5 minutes as needed

#### Subsequent Interventions

**Normal saline infusion**
- Adults: 1–2 L at a rate of 5–10 mL/kg in the first 5 minutes, followed by slow infusion
- Pediatrics: up to 30 mL/kg in the first hour

**Epinephrine infusion**
- If patient is NOT responding to epinephrine injections and volume resuscitation:
  - Adults: epinephrine infusion (1 mg in 250 mL D,W);
  - 1–4 mcg/min, titrating based on clinical response or side effects
  - Pediatrics: epinephrine infusion (0.6 × body weight [in kg]) = number of mg diluted to a total of 100 mL normal saline:
    - 1 mL/hour delivers 0.1 mcg/kg/min

#### Other Considerations After Epinephrine and Fluids

**Diphenhydramine**
- Adults: 25–50 mg IV or IM
- Pediatrics: 1–1.25 mg/kg (maximum of 300 mg/24 hour)

**Ranitidine**
- Adults: 50 mg in D,W 20 mL IV over 5 minutes
- Pediatrics: 1 mg/kg (up to 50 mg) in D,W 20 mL IV over 5 minutes

**Inhaled β-agonist (bronchospasm resistant to epinephrine)**
- 2–5 mg in 3 mL of normal saline, nebulized, repeated as needed

**Dopamine (hypotension refractory to fluids and epinephrine)**
- 2–20 mcg/kg/min titrated to maintain systolic blood pressure > 90 mm Hg

**Hydrocortisone (severe or prolonged anaphylaxis)**
- Adults: 250 mg IV (prednisone 20 mg can be given orally in mild cases)
- Pediatrics: 2.5–10 mg/kg/24 hours

D,W, dextrose 5% in water; IM, intramuscularly; IV, intravenously.

1. Place a drop of each test material on the volar surface of the forearm.
2. Prick the skin with a sharp needle inserted through the drop at a 45° angle, gently tenting the skin in an upward motion.
3. Interpret skin responses after 15 minutes.
4. A wheal at least 2 × 2 mm with erythema is considered positive.
5. If the prick test is nonreactive, proceed to the intradermal test.
6. If the histamine control is nonreactive, the test is considered uninterpretable.

**B. Intradermal Skin Testing**

</table>

1. Inject 0.02–0.03 mL of each test material intradermally (amount sufficient to produce a small bleb).
2. Interpret skin responses after 15 minutes.
3. A wheal at least 6 × 6 mm with erythema and at least 3 mm greater than the negative control is considered positive.
4. If the histamine control is nonreactive, the test is considered uninterpretable.

**Antihistamines may blunt the response and cause false-negative reactions.**

Patient Encounter 1

A 72-year-old man with weight of 137 lb (62 kg) was admitted to a general medicine unit 9 days ago for an upper gastrointestinal bleed. Overnight, he spiked a fever of 104°F (40.0°C) and now has difficulty breathing. A preliminary diagnosis of hospital-acquired pneumonia is made. The medical record states the patient indicated on admission that he does not remember if he has any drug allergies. A combination of piperacillin/tazobactam and vancomycin is ordered. About 10 minutes after the start of the piperacillin/tazobactam infusion, the patient appears agitated and is having greater difficulty breathing. A family member hits the nurse call button.

What type of allergic reaction is the patient most likely having?
What is the first drug (dose and schedule) that should be administered?
What subsequent interventions may be necessary in this patient?

Table 54–5

Multiple Antibiotic Allergies: Obtaining Background Information

For each antibiotic to which the patient claims to be allergic, gather the following information:
- What type of infection was being treated?
- Have you ever received the drug without experiencing a reaction?
- How many times have you received the drug and experienced a reaction?
- Was there any permanent damage?

For each antibiotic the patient has received and does not claim allergy, gather the following information:
- What was the last type of infection being treated?
- What was the drug dose and route of administration?
- Have you received this drug more than once without reactions?

Other information to be gathered:
- Have you had adverse reactions to any other drugs? If so, give dates and describe the reaction.
- Document any risk factors for allergic reactions such as chronic rhinconjunctivitis, urticaria/angioedema, and anaphylaxis. Remember that patients with gastric discomfort or bruising from these agents may describe themselves as being allergic; however, these are not allergic or pseudoallergic reactions.

Two specific conditions—aspirin-exacerbated respiratory disease (AERD) and chronic idiopathic urticaria—are important because they are commonly seen. AERD may include asthma, rhinorrhea, nasal congestion, conjunctivitis, laryngospasm, and asthma. Chronic idiopathic urticaria may also be seen with aspirin or NSAID-induced pseudoallergic reactions.

Drugs are so widely used, with much over-the-counter use, the health care professional must have a basic understanding of the types of reactions that can occur and how to prevent them. Three types of reactions occur: bronchospasm with rhinconjunctivitis, urticaria/angioedema, and anaphylaxis. Remember that patients with gastric discomfort or bruising from these agents may describe themselves as being allergic; however, these are not allergic or pseudoallergic reactions.

Table 54–5 outlines a series of questions that can be useful in developing an effective treatment plan. If available and indicated, skin testing may be useful to complete the puzzle. Often with careful assessment, an antibiotic of choice may be used when the patient’s initial history would have ruled it out. Based on data gathered, the patient’s record should reflect antibiotics safe to use if needed, antibiotics to be avoided, and antibiotics that can be used only after desensitization. Although Table 54–5 was designed with antibiotics in mind, it can be modified for multiple allergy situations.

Aspirin and Nonsteroidal Anti-Inflammatory Drugs

Aspirin and the nonsteroidal anti-inflammatory drugs (NSAIDs) can induce allergic and pseudoallergic reactions. Because these drugs are so widely used, with much over-the-counter use, the health care professional must have a basic understanding of the types of reactions that can occur and how to prevent them. Three types of reactions occur: bronchospasm with rhinconjunctivitis, urticaria/angioedema, and anaphylaxis. Remember that patients with gastric discomfort or bruising from these agents may describe themselves as being allergic; however, these are not allergic or pseudoallergic reactions.
aspirin-induced respiratory disease which may produce severe and even fatal bronchospasm. This class is second only to β-lactams in causing anaphylaxis. Most reactions in this class are due to a complex metabolic pattern which causes increasingly recurrent and severe nasal polyps and often refractory asthma. The metabolic problem is constant once it emerges, accounting for the persistence and difficulty of these clinical problems. The metabolic problem is also capable of causing severe, sometimes fatal, acute reactions to aspirin or many if not all other NSAIDs. Rare reports of non–cross-reactive severe reactions suggest possible specific IgE-mediated reactions to individual NSAIDs, and there are some occurrences of urticaria related to NSAIDs as well. Because aspirin therapy is highly beneficial in primary and secondary prevention in coronary artery disease (CAD), aspirin desensitization should be considered in patients who have had reactions to aspirin. Desensitization is contraindicated in patients who have experienced an aspirin-induced anaphylactoid reaction, hypotension, tachypnea, or altered consciousness. Alternate agents must be used. A comprehensive approach to aspirin-sensitive patients with CAD has been described.²⁹

Radiocontrast Media

**Key Concept** Radiocontrast media may cause serious, immediate pseudoallergic reactions such as urticaria/angioedema, bronchospasm, shock, and death. These reactions have been reduced with the introduction of nonionic, lower osmolality products. Because a small percentage of patients who have reacted previously to radiocontrast media will react if reexposed, several steps (listed below) should be taken to prevent reactions in these patients. These steps should also be followed in patients with high-risk factors: asthmatic patients, patients on β-blockers, and patients with cardiovascular disease.³⁰ The steps are as follows:

- Determine whether the study is essential.
- Be sure the patient understands the risks.
- Ensure adequate hydration.
- Use nonionic, lower osmolar agents.
- Pretreat with prednisone 50 mg orally 13, 7, and 1 hour(s) before the procedure and diphenhydramine 50 mg orally 1 hour before the procedure.

Delayed reactions with these agents occur in 1% to 3% of patients.³⁰ Although reactions are occasionally severe, most are mild and manifest as maculopapular rashes, fixed eruptions, erythema multiforme, and urticarial eruptions.

Opiates

**Key Concept** Opiates (morphine, meperidine, codeine, hydrocodone, and others) stimulate mast cell release directly, resulting in pruritus and urticaria with occasional mild wheezing. Though these reactions are not allergic, many patients state they are “allergic” to one or more of the opiates. Pretreatment with an antihistamine may reduce these pseudoallergic reactions which are rarely, if ever, life-threatening.⁶ Avoiding other mast cell degranulating medications while patients require opiates also reduces the chances of frightening and uncomfortable reactions. Patients may state they are allergic if they have experienced gastrointestinal upset, a common side effect to opiates, with previous exposures. Obtaining a thorough history from the patient will prove useful. If a more serious reaction has occurred, a non-narcotic analgesic should be selected.

Cancer Chemotherapy

Hypersensitivity reactions have occurred with all chemotherapy agents. Reactions are most common with the taxanes, platinum compounds, asparaginases, and epipodophyllotoxins.¹³ Reactions range from mild (flushing and rashes) to severe (dyspnea, bronchospasm, urticaria, and hypotension). IgE-mediated Type I reactions are the most common. To reduce the risk, patients are routinely premedicated with corticosteroids and H₂ and H₁-receptor antagonists. The platinum compounds have produced anemia, probably via a cytotoxic immunologic mechanism.

Insulin

Insulin is one of a very few medications that is itself a whole protein and can induce IgE sensitivity directly. This can result in anaphylaxis. Adverse reactions to insulin also include erythema, pruritus, and indurations, which are usually transient and may be injection site related.³¹ For sensitivity reactions, treatment options include dexamethasone or desensitization. If the reaction is injection site related, a change in delivery system (ie, insulin pump or inhaled insulin) may be helpful.
Anticonvulsants

A wide range of hypersensitivity reactions, ranging from mild maculopapular skin eruptions to severe life-threatening reactions, can occur with anticonvulsants. Aromatic anticonvulsants, primarily phenytoin, carbamazepine, phenobarbital, and primidone as well as some of the newer agents (lamotrigine, oxcarbazepine, felbamate, and zonisamide) can cause a life-threatening syndrome with symptoms including fever, a maculopapular rash, and evidence of systemic organ involvement. The rash may be mild at first but can progress to exfoliative dermatitis, erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. This syndrome is known as anticonvulsant hypersensitivity syndrome (AHS) or drug rash with eosinophilia and systemic symptoms (DRESS). The causative agent should be withdrawn immediately. Cross-sensitivity among aromatic anticonvulsant drugs ranges between 40% and 80%. If a patient is hypersensitive to an aromatic anticonvulsant, a nonaromatic agent (ethosuximide, gabapentin, levetiracetam, topiramate, lacosamide, and valproic acid) or the benzodiazepines may be useful.

Drug Desensitization

Drug desensitization may be undertaken for some drugs in the absence of useful alternative medications. The risk of severe systemic reactions and anaphylaxis associated with desensitization must be compared with the risk of not treating the patient. A thorough evaluation should establish that the drug probably caused the reaction by an allergic mechanism. Because of the dangers involved with drug desensitization, an expert review of the patient’s indication for the drug should be conducted. Consider the possibility that the patient does not really need the drug. Desensitization is a potentially life-threatening procedure and requires continuous monitoring in a hospital setting, with suitable access to emergency treatment and intubation if required. It should only be undertaken under the direction of a physician with suitable training and experience. In such hands, desensitization may present less risk than treatment failure with a less effective alternative medication.

The possibility of readministering a suspected drug may be safely tested by gradual dose escalation in some cases, and there are certainly many more patients who are harmed by inappropriate withholding medications than there are those who suffer significant harm from testing and desensitization.

Only Type I IgE-mediated allergy may be treated by classical desensitization. Desensitization may occur within hours to several weeks, unlike specific immunotherapy injections for inhalant allergy (ie, “allergy shots,” which may take months of therapy before a patient realizes any benefit and years to complete). The mechanism of drug desensitization is poorly understood but produces temporary drug-specific tolerance of the offending drug. Any interruption of therapy of 24 hours or more requires full repeat desensitization, and abrupt significant increases of dosage have been reported to break through the tolerance with some drugs.

The desensitization process probably involves either: (a) cross-linking small subthreshold numbers of bound IgE molecules gradually depleting mast cells of their mediators, or (b) binding of the IgE by monomers or hapten–protein entities that cannot cross-link the antibody. The low doses used at the beginning of all protocols would provide small amounts of antigen, favoring these mechanisms. Both drug-specific IgE and IgG serum concentrations increase after successful desensitization, but skin test positivity generally decreases.

Patient Encounter 3

A 62-year-old man is visiting his new primary care physician for follow-up after being hospitalized for a myocardial infarction 10 days ago. The patient’s father and older brother died from myocardial infarctions when they were in their late 60s. The patient saw a television commercial touting the benefits of aspirin in preventing heart attacks and wants to start taking it immediately. Upon review of the patient’s medical record, his new physician notices that the patient was previously diagnosed with an aspirin allergy. His reaction was primarily a moderate urticaria.

**Does this patient’s potential benefit of aspirin therapy outweigh the risk when considering his history of allergy?**

What course of action would you recommend for this patient?

Oral and intravenous (IV) protocols are available for most drugs in this category, with the oral route producing somewhat milder reactions, but the IV route providing more precision in dosing. IV administration can also be used in unresponsive patients for whom the oral route is not feasible. Protocols generally begin at about 1% of the therapeutic dose and increase in intervals defined by the patient’s reaction and the distribution and metabolism of the drug itself. Half-log10 dose increases (about threefold) are often tolerated.

- Penicillin desensitization is the most common drug desensitization protocol. It is required for penicillin-allergic patients when penicillin is clearly the only treatment option, for example, when syphilis is present in pregnancy. Protocols have been adopted for most antibiotics. Specific procedures for oral and IV penicillin desensitization have been developed.

- Aspirin desensitization is useful in diseases for which low-level antiplatelet action is needed and in the care of patients with aspirin sensitivity and intractable nasal polyps. Lysine aspirin availability in Europe allows desensitization by inhalation at greatly reduced risk. New procedures utilizing ketorolac as a nasal topical application may allow similar reduction of risk in the United States. As with all desensitizations, constant daily administration must be maintained once the desired dose is reached. Several aspirin desensitization protocols have been described in the literature.

All desensitization procedures are expected to produce mild symptoms in the patient at some point, and the patient must be made to understand this before doses are started. Mild sensitivity to the drug still remains, and large dose increases as well as missing doses should be avoided. Late complications, such as urticaria, may occur with Type I desensitization, and serum sickness or hemolytic anemia may also occur with high-dose therapy in allergic, desensitized patients.

Some regimens are designed for outpatient administration over much longer time periods and have been used, for example, with allopurinol dermal reactions. Such late-onset morbilliform reactions, sometimes overlapping with erythema multiforme minor, are difficult to evaluate, because it is often unclear to what extent the patients were at risk for a recurrent reaction.

Severe life-threatening reactions not mediated by IgE, such as Stevens-Johnson syndrome and toxic epidermal necrolysis, are absolute contraindications to testing, desensitization attempts, and readministration.
OUTCOME EVALUATION
To successfully treat a patient with a drug allergy or pseudoallergy, several goals must be accomplished:

- If a reaction occurs, it must be identified and managed quickly.
- The patient should be educated about the reaction.
- True drug contraindications should be avoided if possible.
- Patients should receive the medications they need or a suitable alternative. If this is not possible due to an allergy, desensitization should be considered.
- Patients should always be monitored for adverse drug reactions.

Patient Assessment:
- Based on the medication history, physical examination, and review of systems, determine the likelihood of the reaction being a drug-related problem. See Clinical Presentation and Diagnosis of Allergic and Pseudoallergic Drug Reactions.
- Use questions given in Table 54–5 to establish the nature of the reaction and the likelihood it was caused by the suspected drug. For nonantibiotics, the first question regarding infection type is not needed.
- If appropriate, see Table 54–4 for procedures for performing penicillin skin testing.

Therapy Evaluation:
- Document the reaction, in detail, in the patient’s medical record.
- Recommend an alternative choice if the prescribed drug is contraindicated, and develop a plan to assess safety and effectiveness.
- Consult with health care professionals trained in desensitization if the patient has a true allergy and no acceptable alternative medication is available.

Care Plan Development:
- If reaction is anaphylactic in nature, see Table 54–3.
- The offending drug should be discontinued.
- The treatment goal is relief of symptoms. For mild symptoms such as rash or itching, an antihistamine such as diphenhydramine may be used. For wheezing, bronchodilators such as albuterol may be helpful.
- Recommend an alternative option for the contraindicated drug, or if no alternative is available, consult with health care professional regarding desensitization.
- Educate the patient about the allergy or pseudoallergy so they are able to work with health care providers to avoid the reaction in the future.

Follow-up Evaluation:
- Follow-up daily or more often, if necessary, to assure resolution of the reaction and optimal response to the alternate therapy.

REFERENCES
LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the reasons for solid organ transplantation.
2. Differentiate between the functions of cell-mediated and humoral immunity and how they relate to organ transplant.
3. Describe the roles of antigen-presenting cells in initiating the immune response.
4. Compare and contrast the types of rejection including hyperacute, acute, chronic, and humoral rejection.
5. Define the terms “host–graft adaptation” and “tolerance,” paying close attention to their differences.
6. Discuss the desired therapeutic outcomes and appropriate pharmacotherapy utilized to avoid allograft rejection.
7. Compare and contrast currently available immunosuppressive agents in terms of mechanisms of action, adverse events, and drug–drug interactions.
8. Develop a therapeutic drug-monitoring plan to assess effectiveness and adverse events of the immunosuppressive drugs.
10. Write appropriate patient education instructions and identify methods to improve patient adherence following transplantation.

INTRODUCTION

The earliest recorded attempts at organ transplant date back thousands of years.1 More than a few apocryphal descriptions exist from ancient Egypt, China, India, and Rome describing experimentation with transplantation. However, it was not until the early 1900s that French surgeon, Alexis Carrel, pioneered the art of surgical techniques for transplantation.1 Together with Charles Guthrie, Carrel experimented in artery and vein transplantation. Using revolutionary methods in anastomosis operations and suturing techniques, Carrel laid the groundwork for modern transplant surgery. He was one of the first to identify the dilemma of rejection, an issue that remained insurmountable for nearly half a century.1

Prior to the work of Alexis Carrel, malnourishment was the prevailing theory regarding the mechanism of allograft rejection.1 However, in 1910, Carrel noted that tissue damage in the transplanted organ was likely caused by multiple, circulating biological factors. It was not until the late 1940s with the work of Peter Medawar that transplant immunology became more understood. Medawar was able to define the immunologic nature of rejection using skin allografts. In addition, George Snell observed that grafts shared between inbred animals were accepted but were rejected when transplanted between animals of different strains.1

The seminal work by early transplant researchers eventually led to the concept of histocompatibility.1 Histocompatibility describes the process by which polymorphic genes encode cell membrane antigens that serve as targets for immune response, even within a species. Further research in transplant immunobiology led to a more accurate understanding of the alloimmune response.1

Joseph Murray performed the first successful organ transplant in 1954.1 It was a kidney transplant between identical twins. This was a success in large part because no immunosuppression was necessary due to the fact that donor and recipient were genetically identical. Murray’s success laid the groundwork for modern-day transplantation.

EPIDEMIOLOGY AND ETIOLOGY

Heart

Nearly 6 million Americans are afflicted with heart failure. Cardiac transplantation is the treatment of choice for patients with severe end-stage heart failure. Candidates for cardiac transplantation generally present with New York Heart Association (NYHA) class III or IV symptoms and have an ejection fraction of less than 20% (0.20). The general indications for cardiac transplantation include rapidly declining cardiac...
function, requirement of intravenous (IV) inotropes, and having a projected 1-year mortality rate of greater than 75%. Mechanical support with an implantable left ventricular assist device may be appropriate as bridge therapy while patients await a viable organ. Most heart transplants are orthotopic; however, in certain situations, heterotopic cardiac transplants have been performed. There were 2655 heart transplant procedures done in the United States in 2014. Indications for heart transplant include:

- Cardiomyopathy (ie, dilated myopathy, hypertrophic cardiomyopathy, restrictive myopathy)
- Congenital heart disease
- Coronary artery disease
- Valvular heart disease

Intestine

An intestine transplant may involve the use of an entire intestine or shortened segment. Most intestine transplants completed in the United States involve the transplant of the full organ and are often performed in conjunction with liver transplantation. Although most intestine transplants involve organs harvested from a deceased donor, recent advances in the field have made it possible for living donor intestinal segment transplants. There were 139 intestine transplants (138 deceased donors and 1 living donor) done in 2014. Reasons for intestine transplant include:

- Functional bowel problems (ie, Hirschsprung disease, neuronal intestinal dysplasia, pseudoobstruction, protein-losing enteropathy, microvillus inclusion disease)
- Short gut syndrome (ie, intestinal atresia, necrotizing enterocolitis, intestinal volvulus, massive resection secondary to inflammatory bowel disease, tumors, mesenteric thrombosis)

Kidneys

More than 26 million Americans have chronic kidney disease (CKD), with another 20 million more considered to be at increased risk for kidney disease. End-stage renal disease (ESRD) only constitutes a small portion of those patients with CKD, with more than 640,000 patients diagnosed throughout the United States as of 2012. However, the ESRD population continues to increase. All patients with ESRD should be considered for renal transplantation if they are healthy enough to undergo the surgery.

Most kidney transplants are heterotopic, where the kidney is implanted above the pelvic bone and attached to the patient’s iliac artery and vein. The ureter of the transplant kidney is attached directly to the recipient’s bladder or native ureter. The native kidneys are usually not removed, and data have shown that under most circumstances, removal of the native kidneys does not influence patient survival (ie, survival of the transplant patient, without regard to function or survival of the allograft) and allograft survival. There were 17,108 (11,570 deceased donors and 5,538 living donors) kidney transplants performed in 2014. Reasons for kidney transplant include:

- Congenital, familial, and metabolic disorders (ie, congenital obstructive uropathy, Fabry disease, medullary cystic disease, nephrolithiasis)
- Diabetes mellitus (DM)
- Glomerular diseases (ie, antiglomerular basement membrane disease, focal segmental glomerular sclerosis, IgA nephropathy, hemolytic uremic syndrome, systemic lupus erythematosus, Alport syndrome, amyloidosis, membranous nephropathy, Goodpasture syndrome)
- Hypertension
- Neoplasm (ie, renal cell carcinoma, Wilms tumor)
- Polycystic kidney disease
- Renovascular disease
- Tubular and interstitial diseases (ie, analgesic nephropathy, drug-induced nephritis, oxalate nephropathy, radiation nephritis, acute tubular necrosis, sarcoidosis)

Liver

A liver transplant may involve the use of the entire organ or a segment. The majority of cases involve utilizing the full organ. In recent years, segmental transplants have been conducted using living donors. This procedure requires donation of the left hepatic lobe, which accounts for nearly 60% of the overall liver mass. This type of procedure is possible because the liver can regenerate; therefore, both the donor and recipient, in theory, will have normal liver function shortly after the transplant procedure. There were 6729 (6449 deceased donors and 280 partial lobe-living donors) liver transplants done in 2014. Reasons for liver transplant include:

- Acute hepatic necrosis (ie, chronic or acute hepatitis B or C)
- Biliary atresia
- Cholestatic liver disease/cirrhosis (ie, primary biliary cirrhosis)
- Metabolic disease (ie, Wilson disease, primary oxalosis)
- Neoplasms (ie, hepatoma, cholangiocarcinoma, hepatoblastoma, bile duct cancer)
- Noncholestatic cirrhosis (ie, alcoholic cirrhosis, postnecrotic cirrhosis, drug-induced cirrhosis)

Lungs

Lung transplants may involve deceased donation of two lungs or a single lung. More recently, lobar transplants from blood group–compatible living donors have been performed for a small segment of the population. Most of the lobar transplants have been performed on cystic fibrosis patients. On rare occasions, a simultaneous heart–lung transplant occurs. This type of procedure is reserved for patients with severe pulmonary and cardiac disease. There were 1925 (all deceased donors) lung transplants and 24 simultaneous heart–lung transplant procedures done in 2014. Reasons for lung transplant include:

- α-1-Antitrypsin deficiency
- Congenital disease (ie, Eisenmenger syndrome)
- Cystic fibrosis
- Emphysema/chronic obstructive pulmonary disease
- Idiopathic pulmonary fibrosis
- Primary pulmonary hypertension

Pancreas

The exact nationwide prevalence of all diseases of the pancreas has not been fully quantified; however, DM, both types 1 and 2, affects nearly 21 million people in the United States. Some people suffering from DM may also be afflicted with ESRD. A small percentage of these patients undergo a simultaneous
pancreas-kidney (SPK) transplant, which may be accomplished using organs from deceased or living donors. Transplant of a pancreas may involve either the entire organ or a pancreas segment. Currently, whole-organ transplant is the most common procedure, with a portion of the duodenum often transplanted along with the pancreas. Living donors are often the source of segmental transplants. In recent years, isolation and transplantation of β-islet cells alone have been completed. Islet transplantation is intended to treat organ dysfunction by replacing nonfunctioning islet cells with new ones. Islet transplants are still considered experimental, and long-term benefit and/or risk of this procedure needs to be studied extensively. Future success of islet cell transplantation is dependent on identifying a nontoxic immunosuppressive combination. There were 245 pancreas transplants and 709 SPK procedures done in 2014. 

Reasons for pancreas transplants include:

- DM (ie, type 1 and 2, DM secondary to chronic pancreatitis or cystic fibrosis)
- Pancreatic cancer

PATHOPHYSIOLOGY

**Major Histocompatibility Complex**

The primary target of the immune response after organ transplant is the major histocompatibility complex (MHC). The MHC is a region of highly polymorphic genes located on the short arm of chromosome 6. The human MHC is referred to as human leukocyte antigen (HLA). HLA is a set of glycoproteins expressed on the surface of most cells. These proteins are involved in immune recognition, which is the discrimination of self from nonself, but are also the principal antigenic determinants of allograft rejection.

The HLA have been classified into two major groups, class I and II:

- Class I: expressed on the surfaces of all nucleated cells and recognized by CD8+ cells (ie, cytotoxic T cells).
- The three subclasses of MHC class I are HLA-A, HLA-B, and HLA-C.
- Class II: expressed solely on the surfaces of antigen-presenting cells (APCs). The APCs serve to stimulate CD4+ cells (ie, helper T cells).
- The three subclasses of MHC class II are HLA-DP, HLA-DQ, and HLA-DR.

**T and B Lymphocytes**

Lymphocytes are one of five kinds of white blood cells. Mature lymphocytes are astonishingly diverse in their functions. The most abundant of the lymphocytes are T lymphocytes (ie, T cells) and B lymphocytes (ie, B cells).

**T Lymphocytes**

T cells play a major role in the cell-mediated immune response. These cells are produced in the bone marrow, but mature in the thymus, hence the abbreviation “T.” There are three recognized subclasses of T cells: cytotoxic T cells, helper T cells, and regulatory T cells:

- Cytotoxic T cells (CD8+) promote target cell destruction by activating cellular apoptosis or killing the target cell via the release of cytotoxic proteins.
- Helper T cells (CD4+) are the great communicators of the immune response. Once activated, they proliferate and secrete cytokines that regulate effector cell function. Some helper T cells secrete cytokines that recruit cytotoxic T cells, B cells, or APCs, whereas others secrete cytokines that turn off the immune response.
- Regulatory T cells, or suppressor T cells, suppress the activation of an immune response.

**B Lymphocytes**

B cells play a large role in the humoral immune response. In humans, B cells are produced and mature in the bone marrow. The human body produces several types of B cells. Each B cell is unique, with a distinctive cell surface receptor protein that binds to only one particular antigen. Once B cells encounter their antigen and receive a cytokine signal from helper T cells, they can further differentiate into one of two cells, plasma cells or memory B cells. Plasma cells secrete antibodies that induce the destruction of target antigens through complement recruitment and/or opsonization. Memory B cells play an important role in long-term immunity, as they are capable of rapidly responding to subsequent exposures to their target antigen.

**Antigen-Presenting Cells**

An APC is a cell that displays a foreign antigen complexed with MHC on its cell surface. Its major responsibility is to present these foreign antigens to T cells. T cells can identify this complex using their T-cell receptors (TCRs). There are three main types of APCs: dendritic cells (DCs), macrophages, and activated B cells. DCs are present in tissues that are in contact with the environment, such as skin and the lining of the nose, lungs, stomach, and intestines. They are responsible for phagocytosis. After which, they express the foreign antigen on their cell surface and then migrate to lymphoid tissues to interact with T and B cells to initiate the immune response. Macrophages’ main role is removal of pathogens and necrotic debris. However, like DCs, macrophages also phagocytize antigens. The first time an antigen is encountered, the DCs and macrophages act as the primary APCs. However, if the same antigen is encountered again, memory B cells become the most important APC because they initiate the immune response quickly after antigen presentation. It appears that both the DCs and macrophages have the most activity in terms of allore cognition.

**Allorrecognition**

Recognition of the antigens displayed by the transplanted organ (alloantigens) is the prime event that initiates the immune response against the allograft. There are currently two accepted pathways for allorrecognition:

- Direct pathway: Donor APCs migrate out of the allograft into the recipient’s lymph nodes and present donor MHC molecules to the recipient’s T cells.
- Indirect pathway: Recipient APCs migrate into the graft and phagocytize alloantigens. The recipient’s APCs present donor MHC molecules to the recipient T cells in lymph nodes.

**T-Cell Activation**

Whether it is by direct or indirect pathways, in order for a T cell to become activated against the allograft, two interactions or signals must take place between the APCs and the recipient’s T cells:

- Signal 1 is the interaction of the TCR with the foreign antigens presented by APCs.
Signal 2 is an interaction between one of several clinical symptoms:

- Fever, impaired gas exchange, SOB, malaise, anxiety
- Acute Rejection
- Fever, graft tenderness, decreased urine output, malaise, hypertension, weight gain, edema
- Hyperacute Rejection
- Decreased FEV, infiltrate on CXR, biopsy positive for
- Fever, graft tenderness and swelling, abdominal pain, ileus, and malaise

Laboratory Signs

- Leukocytosis, biopsy positive for mononuclear infiltrates
- Increased SCr, BUN, leukocytosis, biopsy positive for lymphocytic infiltration
- There are no reliable biochemical markers for intestine transplant rejection, but biopsies may be helpful
- Abnormal LFTs, increased bilirubin, alkaline phosphate, transaminases, biopsy positive for mononuclear cell infiltrate with evidence of tissue damage
- Decreased FEV, infiltrate on CXR, biopsy positive for lymphocytic infiltration
- Increased FBS, leukocytosis, decreased human C-peptide and urinary amylase levels

- BUN, blood urea nitrogen; CXR, chest x-ray; DOE, dyspnea on exertion; FBS, fasting blood sugar; FEV, forced expiratory volume; GI, gastrointestinal; LFTs, liver function tests; SCr, serum creatinine; SOB, shortness of breath.

Mechanisms of Acute Rejection

After activation, cytotoxic T cells emerge from lymphoid organs to infiltrate the graft and trigger the immune response. These cells induce graft destruction via two mechanisms: (a) secretion of cytotoxic proteins (ie, perforin, granzyme) and (b) induction of cellular apoptosis through interaction. Besides the cytotoxic T cells, several other cell lines may play a role in allograft destruction, including B cells, granulocytes, and natural killer cells.

Types of Rejection

**Hyperacute Rejection**

Hyperacute rejection is an immediate recipient immune response against the allograft due to the presence of preformed recipient antibodies directed against the donor’s HLA. This type of reaction generally occurs within minutes of transplantation. The organ must be removed immediately to prevent severe systemic responses. In the case of cardiac or lung transplantation in which the organ cannot be promptly removed, short-term mechanical circulatory support is required until an alternative organ becomes available. Those patients at highest risk for hyperacute rejection include any patients that have preformed HLA or ABO blood group antibodies, including patients with a history of previous organ transplant or multiple blood transfusions, as well as women who have had children. Hyperacute rejection has been largely eliminated due to routine pretransplant surveillance testing.

**Acute Rejection**

Acute rejection is a cell-mediated process that generally occurs early posttransplant; however, it can occur at any time after transplant. This reaction is mediated through alloreactive T cells, as discussed above. Organ-specific signs and symptoms of acute rejection can be seen in Table 55–1.

**Antibody-Mediated Rejection**

- Antibody-mediated rejection (AMR) is the process of creating graft-specific antibodies.
- This type of rejection occurs less frequently than cell-mediated acute rejection. Histologic findings are similar to those of hyperacute rejection, but the severity of rejection is usually less with AMR. AMR is generally characterized by deposition of immunoglobulins and complement in allograft tissues. However, AMR may be diagnosed without the presence of complement. Treatment for this type of rejection is not well defined; however, several reports have shown that treatments such as plasmapheresis, immunoglobulin therapy, rituximab, bortezomib, or eculizumab may be effective.

**Chronic Rejection**

Chronic rejection has traditionally been thought of as a slow, insidious form of acute rejection, resulting in worsening organ function over time. The exact immunologic processes of chronic rejection are poorly understood; however, many believe that both the cell-mediated and humoral immune systems and drug-induced toxicities play a vital role in its development. Currently, retransplantation is the only effective treatment option.

**Host–Graft Adaptation**

The term “host–graft adaptation” describes the decreased immune response against the allograft over time. This phenomenon is evident by the reduced incidence of acute rejection episodes seen months after transplantation. In theory, host–graft adaptation is thought to be secondary to a weakened T-cell response to donor antigens while patients receive maintenance immunosuppression.

**Tolerance**

Tolerance is the process that allows organ-specific antigens to be accepted as self. This would mean the immune system would cease to respond to the allograft and immunosuppressive medications would not be required. Immune tolerance has been
achieved in the lab, but has yet to be successfully accomplished in humans.1

**Immunologic Barriers to Transplantation**

One of the more common barriers to successful transplantation is the presence of preformed HLA antibodies or ABO blood group incompatibility.2 In cases in which these antibodies exist, if they are not adequately removed prior to transplant, they are likely to result in AMR and poor graft survival. To improve outcomes, assessment of pretransplant immune risk factors plays an important role in the prevention of immune-mediated allograft injuries. The introduction of pretransplant cross-matching and the use of ABO-compatible donors has largely eliminated hyperacute rejection episodes. However, these immunologic barriers are present in several potential recipients with willing organ donors, and patients are left to wait for a deceased donor or undergo pretransplant immunomodulation in an attempt to prevent these antibodies from affecting the allograft.4

**► ABO Incompatibility**

The expanding deceased donor waiting list encouraged some centers to evaluate the use of ABO desensitization protocols in order to transplant patients with ESRD that had willing but ABO-incompatible donors.4 The desensitization protocol most commonly used in the United States involves reducing ABO antibody titers through plasmapheresis with IV immune globulin (IVIG). Use of plasma exchange to achieve an ABO antibody titer of less than 1:8 to 1:32 has resulted in long-term renal transplant results that are comparable to those of ABO-compatible transplants, despite an incidence of acute AMR that approaches 10% to 30%.4

**► HLA Sensitization**

Evaluation of the presence or absence of alloantibodies and T-cell activities to HLA antigens plays a significant role in individualization of immunosuppression.4 A patient’s degree of sensitization is often reported as the percentage of panel-reactive antibodies (PRA), which is an estimate of the likelihood of a positive crossmatch to a pool of potential donors. Advancement in HLA antibody screening and identification through flow cytometry or solid-phase multiplex platforms has overcome many of the issues stemming from older methods of PRA calculations. Patients are considered to be highly sensitized to HLA if they have a PRA of greater than or equal to 80%, making them less likely to receive a deceased donor organ. Patients with higher PRAs and preformed antibodies have poorer long-term allograft survival. Although PRA is a sensitive test and has predictive value, lymphocytes directly obtained from the donor is a superior method of immune monitoring. The assay is aimed to detect the presence of antibodies directed against the HLA antigens of the donor. In this setting, the presence of donor-specific antibodies (DSA) is identified. In one study, allograft survival was significantly lower in patients with DSA.5 Thus detecting DSA and the presence of high PRA may indicate the need to enhance immunosuppression to improve posttransplant outcomes and allograft survival.4

Like ABO incompatibilities, it is possible to desensitize patients against a willing donor despite the presence of DSA or those awaiting a deceased donor transplant with a broad array of preformed anti-HLA antibodies (PRA greater than or equal to 30%).4 There are two general protocols used for HLA desensitization: high-dose IVIG and low-dose IVIG with plasmapheresis. Despite the relatively high degree of AMR seen in desensitized patients, this population of patients has acceptable short-term patient and allograft survival. Unfortunately, the long-term results for graft and patient outcomes using either of these two protocols are unknown.5

**TREATMENT**

**Desired Outcome**

- **KEY CONCEPT** The major focus of pharmacotherapy in transplantation is to achieve long-term patient and allograft survival.1,3,5,6 Short-term outcomes (eg, acute rejection rates, 1-year graft survival) have improved significantly since the first successful transplant due to an improved understanding of the immune system and enhancements in surgical techniques, organ procurement, immunosuppression, and posttransplant care. Despite the success in improving short-term outcomes, the frequency of graft loss remains higher than desired.1,3,5,6

It is imperative that transplant practitioners be aware of the specific advantages and disadvantages of the available immunosuppressants, as well as their adverse reactions and drug–drug interaction (DDI) profiles. There are generally three stages of medical immunosuppression: (a) induction therapy, (b) maintenance therapy, and (c) treatment of rejection. **KEY CONCEPT** Overall, the immunosuppressive regimens utilize multiple medications working on different targets of the immune system. Please refer to Table 55–2 for a list of all available immunosuppressive agents.1,5,6

**Immunosuppressive Therapies—Induction Therapy**

- **KEY CONCEPT** The goal of induction therapy is to provide a high level of immunosuppression in the early posttransplant period, when the risk of acute rejection is highest.2 This stage of immunosuppression is initiated intraoperatively and is concluded within the first 1 to 10 days after transplantation. Antibody induction therapy is not a mandatory stage of recipient immunosuppression and is typically predicated on immunologic risk. However, since acute rejection is a major concern in solid organ transplant recipients and its impact on chronic rejection is undeniable, induction therapy is often considered essential in some organs to optimize outcomes.5

**► Goals of Induction Therapy**

- **KEY CONCEPT** First, the induction agents are highly immunosuppressive, allowing for significant reductions in acute rejection and improved 1-year graft survival.3 Second, due to their unique pharmacologic effect, these agents are often considered essential in patients at high risk for poor short-term outcomes, such as patients with preformed antibodies, history of previous transplants, multiple HLA mismatches, or transplantation of organs with prolonged cold ischemic time, or from expanded-criteria donors. Specifically in renal transplantation, induction therapy plays an important role in preventing early-onset calcineurin inhibitor (CNI)–induced nephrotoxicity. With induction therapy, CNI initiation can be delayed until the graft regains some degree of function. Induction therapy is imperative when employing corticosteroid sparing or avoidance protocols.5

The improved short-term outcomes gained from induction therapy come with a degree of risk.5 By using these highly immunosuppressive agents, particularly the antilymphocyte antibodies (ALA; the antithymocyte antibodies and alemtuzumab), the ability to mount a cell-mediated immune response is significantly reduced, which increases the risk of opportunistic infections and malignancy. Cytokine release syndrome is a common
complication of T-cell depleting agents and may require premedications before infusions.\textsuperscript{5}

> **Currently Available Induction Therapies**

- **Basiliximab** Basiliximab is a chimeric monoclonal antibody that acts as an IL-2 receptor antagonist.\textsuperscript{5,7} These receptors are present on almost all activated T cells. Basiliximab inhibits IL-2–mediated activation of lymphocytes, which is an important step in T-cell clonal expansion.

  The dose of basiliximab is 20 mg IV given 2 hours prior to the transplant, followed by a second 20-mg dose on postoperative day 4.\textsuperscript{5,7} This dosing schedule can be used for both children greater than or equal to 35 kg (77 lb) and adults. Two 10 mg doses with the same dosing schedule should be used for children less than 35 kg (77 lb). There are no specific dosage adjustments needed in renal or hepatic impairment.\textsuperscript{5,7}

  The incidence of all adverse reactions with basiliximab was similar to placebo in trials. There are no reported DDIs with basiliximab.\textsuperscript{5,7}

- **Antithymocyte Globulin Equine** Antithymocyte globulin equine (e-ATG) is a polyclonal antibody that contains antibodies against several T-cell surface markers. After binding to T cells, e-ATG promotes cellular depletion through opsonization and complement-mediated T-cell lysis.\textsuperscript{5,7} The common dosing strategy for e-ATG when used for induction therapy is 10 to 30 mg/kg/day IV for 3 to 14 days.\textsuperscript{5,7}

  After T-cell lysis there is a cytokine release. Due to this phenomenon, e-ATG is associated with several adverse reactions.\textsuperscript{5,7}

  - The most common of these include fever (63%), chills (43.2%), headache (34.6%), back pain (43.2%), nausea (28.4%), diarrhea (32.1%), dizziness (24.7%), malaise (3.7%), leukopenia (29.6%), and thrombocytopenia (44.4%). The overall incidence of opportunistic infections is 27.2%, with cytomegalovirus (CMV) disease occurring in 11.1% of patients. There are currently no reported pharmacokinetic DDIs with this agent.\textsuperscript{5,7}

- **Antithymocyte Globulin Rabbit** Antithymocyte globulin rabbit (r-ATG) is also a polyclonal antibody that induces T-cell clearance, but more importantly, it alters T-cell activation, homing, and cytotoxic activities.\textsuperscript{7} Compared with e-ATG, r-ATG causes less cell lysis. It is also believed that r-ATG plays a role in inducing T-cell apoptosis. This agent is typically dosed at 1.5 mg/kg/day and is usually administered for 3 to 10 days after transplantation.\textsuperscript{5} Many renal transplant centers aim to initiate the first dose intraoperatively to reduce organ reperfusion injury.\textsuperscript{8}

Adverse reactions are common and may include fever (63.4%), chills (57.3%), headache (40.2%), nausea (36.6%), diarrhea (36.6%), malaise (13.4%), dizziness (8.5%), leukopenia (57.3%), thrombocytopenia (36.6%), and generalized pain (46.3%).10,13 The incidence of infection is 36.6%, with CMV disease occurring in 13.4% of patients. There are no reported DDIs with the use of r-ATG at this time.57

Alemtuzumab

Alemtuzumab is a recombinant DNA-derived monoclonal antibody that binds to CD52, which is present on most B and T lymphocytes, macrophages and natural killer (NK) cells, and a subpopulation of granulocytes.52 After complexing with the CD52 cell surface marker, alemtuzumab induces an antibody-dependent cell lysis. This agent produces a rapid and extensive lymphocyte depletion that may take several months to years to return to pretransplant levels. Although it is not Food and Drug Administration (FDA) approved for use in organ transplantation, studies have demonstrated a dose of 30 mg IV or SC at the time of transplant to be effective in preventing acute rejection.5

Alemtuzumab has been associated with serious adverse reactions that include anemia (47%), neutropenia (70%), thrombocytopenia (52%), headache (24%), dysesthesias (15%), dizziness (12%), nausea (54%), vomiting (41%), diarrhea (22%), infusion-related reactions (15% to 89%), and infection (37%; CMV viremia occurred in 15% of patients).7 The FDA recommends that premedication with acetaminophen and oral antihistamines is advisable to reduce the incidence of infusion-related reactions.5

Comparative Efficacy—Induction Therapy Agents

Improvements in short-term outcomes gained from the use of induction therapies cannot be denied. However, despite these advances, use of induction therapy has not impacted long-term allograft function or survival. There are a few studies that help to delineate the ideal induction therapy agent. Studies comparing r-ATG and e-ATG show that r-ATG is more effective in lowering acute rejection rates and improving 1-, 5- and 10-year allograft outcomes.8,14 Conversely, a study evaluating the use of basiliximab versus r-ATG demonstrated similar short-term efficacy between both groups.13 However, other analyses of these two agents demonstrated similar results for allograft and patient survival, but a benefit for r-ATG in lowering incidence of acute allograft rejection.13,14 A more recent analysis showed that alemtuzumab improved transplant outcomes when compared with basiliximab in patients with a low immunologic risk, and similar outcomes compared to r-ATG in patients with high immunologic risk.15 When choosing an agent for induction therapy, one must weigh the risks versus benefits. Overall, the ALAs are considered to be most effective, but are associated with a higher incidence of infectious disease and malignancy.5

Immunosuppressive Therapies—Maintenance Therapy

The goals of maintenance immunosuppression are to prevent rejection and optimize patient and graft survival.6 Antirejection medications require careful selection and dose titration to balance the risks of rejection with those of toxicities. Common maintenance immunosuppressive agents can be divided into five classes:

- Calcineurin inhibitors (CNI; cyclosporine and tacrolimus)
- Antiproliferatives (azathioprine and the mycophenolic acid [MPA] derivatives)
- Target of rapamycin (ToR) inhibitors (sirolimus and everolimus)
- Corticosteroids
- Costimulatory blockade (belatacept)

Maintenance immunosuppression is generally achieved by combining two or more medications from the different classes, specifically targeting unique components of the immune response.6 Please refer to Figure 55–1 for a schematic representation of these different drug mechanisms and Figure 55–2 for an example protocol for administration of immunosuppressive medications posttransplant. This method of medication selection also minimizes toxicities by choosing agents with different adverse event profiles. Immunosuppressive regimens vary between organ types and transplant centers, but most often include a CNI with an adjuvant agent, plus or minus corticosteroids. Selection of an immunosuppressive regimen should be

Patient Encounter Part 1

HPI: A 59-year-old woman presents to your transplant center for a living unrelated renal transplant.

PMH: ESRD secondary to diabetes mellitus type 2; obesity (she has lost weight in order to get her BMI less than 35 to be approved for renal transplantation); hypertension; hyperlipidemia; insomnia; gout (has had three episodes of gout in the past 12 months); secondary hyperparathyroidism

FH: Father died from a heart attack 3 years ago; mother is alive and living with a history of breast cancer

SH: Does not work due to poor health, but was formerly a dental hygienist. She admits to social alcohol use (one or two drinks per week) and denies any tobacco and IV drug use

Admission Meds: Diltiazem ER 120 mg by mouth once a day; irbesartan 100 mg by mouth once a day; furosemide 20 mg by mouth twice a day; atorvastatin 20 mg by mouth once a day; zolpidem 10 mg by mouth once a day at bedtime; calcitriol 0.25 mg by mouth once a day; sevelamer carbonate 1600 mg with each meal and 800 mg with each snack; Epo 4000 units IV every hemodialysis session; insulin glargine 22 units administered in the evening; insulin aspart 4 units with each meal and a sliding scale (dependent on blood sugars)

Allergies: Sulfa—hives

Labs: CMV serostatus: donor is CMV IgG positive; CMV serostatus: recipient is CMV IgG negative; EBV serostatus: donor is EBV IgG positive; EBV serostatus: recipient is EBV IgG negative

Identify your treatment goals for this patient.

Create a plan for induction therapy (ie, would you recommend induction therapy, and if so, which agent?).
Calcineurin Inhibitors

Therapeutic concentrations traditionally been obtained to help monitor for efficacy and safety. In the event of a suspected drug reaction, one should be monitored closely. The CNIs work by complexing with cytoplasmic proteins (cyclosporine with cyclophilin and tacrolimus with FK binding protein). These complexes inhibit calcineurin phosphatase, which results in reduced IL-2 gene transcription and a reduction in IL-2 synthesis. This diminishes T-cell activation.

Cyclosporine Cyclosporine USP was first approved in 1983, but was associated with a variable oral absorption. The development of a newer formulation, cyclosporine microemulsion USP (ie, modified), introduced in 1994, allowed for a more consistent drug exposure. Cyclosporine modified is the formulation of choice for most transplant centers utilizing cyclosporine due to the previously mentioned benefit. The two formulations are not interchangeable.

Cyclosporine whole-blood trough concentrations (C0) have traditionally been obtained to help monitor for efficacy and safety. Therapeutic C0 may range from 50 to 400 ng/mL (50–400 mcg/L or 42–333 nmol/L). Target levels should be individualized for each patient, usually depending on the organ transplanted, patient’s condition, method of assay (liquid chromatography coupled to tandem mass spectrometry [LC-MS/MS], monoclonal, polyclonal), and time since transplantation. Newer studies suggest that monitoring of concentrations at 2 hours postdose (C2) correlates better with toxicity and efficacy when compared with C0.

Tacrolimus Tacrolimus is the second CNI and was approved in 1997. Oral starting doses of tacrolimus range from 0.1 to 0.2 mg/kg/day in two divided doses. Tacrolimus is available in 0.5-, 1-, and 5-mg capsules and as an injectable. Two once daily tacrolimus formulations are also available. Tacrolimus C0 should be monitored and maintained between 5 and 15 ng/mL (5 and 15 mcg/L or 6 and 18 nmol/L), again depending on the transplanted organ, patient’s condition, and time since transplant. The tacrolimus IV formulation is usually avoided due to the risk of anaphylaxis, because of its castor oil component, and nephrotoxicity. Doses for IV administration are recommended to start at 0.01 mg/kg/day. In an effort to avoid IV tacrolimus, many transplant centers utilize sublingual (SL) tacrolimus in their patients unable to receive the medication by mouth.

Adverse Drug Reactions One of the major disadvantages of the CNIs is their ability to cause nephrotoxicity. Acute nephrotoxicity has been correlated with high doses and is usually reversible. Chronic CNI toxicity, however, is typically irreversible and is linked to chronic drug exposure. Table 55–3 expands on the more common calcineurin inhibitor–associated adverse events.

Comparative Efficacy—Calcineurin Inhibitors Even though cyclosporine and tacrolimus are both CNIs, there are several
FIGURE 55–2. Example protocol of immunosuppressive medication use in organ transplantation. Center-specific protocols may use rabbit antithymocyte immunoglobulin (RATG), an interleukin-2 receptor antagonist (IL-2RA), or no induction therapy. In any situation, patients receive IV methylprednisone prior to, during, or immediately following the transplant operation. The patient then will begin the maintenance immunosuppressive regimen. The center-specific protocol will specify which calcineurin inhibitor (cyclosporine or tacrolimus) is used in combination with mycophenolate mofetil or sirolimus, with or without steroids. Patients then are monitored for signs and symptoms of rejection. If rejection is suspected, a biopsy can be done for definitive diagnosis, or the patient may be treated empirically for rejection. Empirical treatment generally involves administration of corticosteroids. If signs and symptoms of rejection are resolved with empirical therapy, the patient will continue to be monitored according to the center-specific protocol. If rejection is confirmed by biopsy, treatment may be based on the severity of rejection. High-dose corticosteroids are used most frequently for mild to moderate rejection. RATG can be used for moderate to severe rejections or steroid-resistant rejections. Protocols and algorithms may differ across transplant centers. (ATG, antithymocyte globulin; BUN, blood urea nitrogen; CNI, calcineurin inhibitor; CSA, cyclosporine; IV, intravenous; LFT, liver function test; MPA, mycophenolic acid; SCR, serum creatinine; SRL, sirolimus; TAC, tacrolimus.) (From Schonder KS, Johnson HJ. Solid Organ Transplantation. In: DiPiro JT, Talbert RL, Yee GC, et al., eds. Pharmacotherapy: A Pathophysiologic Approach. 9th ed. New York: McGraw-Hill; 2014:1419.)
differences between the two. A meta-analysis comprised of 30 trials and 4102 patients comparing cyclosporine to tacrolimus in kidney transplantation, showed tacrolimus was associated with significantly lower risk of allograft loss at 6 months and lower rates of acute rejection at 1 year. Tacrolimus is the primary CNI in many transplant centers, due in large part to a more favorable adverse reaction profile.

|                   |                           |                                                 | -Oral surgery (gum resection)                                                                     |
|                   |                           |                                                 | -Modify regimen (change to tacrolimus or non-CNI containing regimen)                            |
|                   |                           |                                                 |                                                                                                  |

BUN, blood urea nitrogen; CCB, calcium channel blocker; CNI, calcineurin inhibitor; SCr, serum creatinine; ToR, target of rapamycin.

*Modifying the immunosuppressive regimen increases risk for rejection, even in stable patients. This option should be chosen cautiously and be implemented with proper monitoring and follow-up.

*Tacrolimus is also associated with hypertension and hyperlipidemia, but to a much lower extent compared to cyclosporine.

*Cyclosporine is also associated with hyperglycemia and neurotoxicities, but to a much lower extent compared to tacrolimus.

#### Antiproliferatives

These agents are considered to be adjuvant to the CNIs or ToR inhibitors.

**Azathioprine** Azathioprine was approved in 1968 as an adjunct immunosuppressant in renal transplant. It is available in oral and IV dosage forms. Prior to the advent of cyclosporine, the
combination of azathioprine and corticosteroids was the mainstay of immunosuppressive therapy. Over the past 10 years, the use of azathioprine declined markedly due to the superiority of the MPA derivatives. 

Azathioprine is a prodrug for 6-mercaptopurine (6-MP), a purine analog. 6-MP acts as an anti-metabolite and inhibits DNA replication with a resultant reduction in T-cell proliferation. The typical oral dose of azathioprine for organ transplantation is 1 to 5 mg/kg once a day. Dose reductions due to severely impaired renal function may be necessary since 6-MP and its metabolites are renally eliminated. Trough concentrations of 6-MP are not monitored; however, most clinicians often monitor for signs of myelosuppression. Myelo-suppression (mainly leukopenia and thrombocytopenia) is a frequent, dose-dependent and dose-limiting complication (greater than 50% of patients) that often prompts dose reductions. Other common adverse events include hepatotoxicity (2%–10%) and adverse gastrointestinal (GI) events (10%–15%; mostly nausea and vomiting). Importantly, pancreatitis and veno-occlusive disease of the liver occur in less than 1% of patients following chronic azathioprine therapy.

**Mycophenolic Acid Derivatives** Mycophenolate mofetil was approved in 1995 and enteric-coated MPA in 2004. Both agents are considered adjunctive immunosuppressants. Both mycophenolate mofetil and enteric-coated MPA are prodrugs for MPA. MPA acts by inhibiting inosine monophosphate dehydrogenase, a vital enzyme in the de novo pathway of purine synthesis. Inhibition of this enzyme prevents the proliferation of most cells that are dependent on the de novo pathway for purine synthesis, including T and B cells.

Mycophenolate mofetil is available in 250-mg and 500-mg capsules, an oral suspension (100 mg/mL; in cherry syrup), and as an injectable. The recommended starting dose of mycophenolate mofetil is 1000 to 1500 mg given twice daily. The conversion between oral and IV mycophenolate mofetil is 1:1. Enteric-coated MPA is available in 180-mg and 360-mg tablets.

The appropriate equimolar conversion between mycophenolate mofetil and enteric-coated MPA is 1000 mg of mycophenolate mofetil to 720 mg of enteric-coated MPA. The recommended starting dose of enteric-coated MPA is 720 mg given twice daily. Conversion of mycophenolate mofetil to enteric-coated MPA has been proven safe. MPA C_{10} can be monitored; however, it is not routinely recommended.

The most common adverse events associated with these agents are GI (18%–54%; diarrhea, nausea, vomiting, and gastritis) and myelosuppression (20%–40%). Despite its enteric coating, enteric-coated MPA has the same degree of GI adverse events as mycophenolate mofetil. However, recent data suggest there is a benefit in converting patients with documented mycophenolate-induced GI disease from mycophenolate mofetil to enteric-coated MPA.

**Comparative Efficacy—Antiproliferatives** Due to the results of several studies, the MPA derivatives have replaced azathioprine as the primary antiproliferative agent. The MPA derivatives are generally considered to provide a more specific immunosuppressive effect compared with azathioprine. Mycophenolate mofetil and enteric-coated MPA have similar safety and efficacy data in renal transplant recipients. The decision to choose one agent over another is a purely practitioner-dependent preference.

**Target of Rapamycin Inhibitors**

Sirolimus inhibits T-cell activation and proliferation by binding to and inhibiting the activation of the mammalian ToR, which suppresses cellular response to IL-2 and other cytokines (ie, IL-4, IL-15). Studies have shown that sirolimus may be used safely and effectively concomitantly with either cyclosporine or tacrolimus instead of an antiproliferative. Sirolimus can also be used as an alternative agent for patients who do not tolerate CNIs due to nephrotoxicity or other adverse events. At this time, the most exciting data for sirolimus point to its ability to prevent long-term allograft dysfunction when used as a substitute for the CNIs in renal transplant recipients.

Sirolimus is available in 0.5-mg, 1-mg, and 2-mg tablets and a 1-mg/mL oral solution. Although some may elect not to do a loading dose, the package insert indicates the current approved dosing regimen for sirolimus is a 6-mg loading dose followed by a 2-mg/day maintenance dose. Use of a sirolimus loading dose of 5 to 15 mg/day for 1 to 3 days will allow for a more rapid achievement of adequate immunosuppression. Maintenance doses of sirolimus usually range from 1 to 10 mg/day given once daily. Sirolimus blood C_{10} should be maintained between 3 and 10 ng/mL (3 and 10 mcg/L or 3 and 11 nmol/L), depending on the institution-specific protocols. Of note, sirolimus has a half-life of approximately 62 hours, which means that it will not reach steady state after dosage changes for several days.

Everolimus Everolimus is a derivative of sirolimus and has the same mechanism of action. Everolimus is only indicated for prevention of rejection in low- to moderate-risk renal and liver transplant recipients. This agent is available in 0.25-mg, 0.5-mg, and 0.75-mg tablets. The recommended starting dose of everolimus is 0.75 to 1 mg twice daily without the need for a loading dose. Maintenance everolimus doses should be maximized to achieve a C_{10} goal of 3 to 8 ng/mL (3–8 mcg/L or 3–8 nmol/L). With a significantly shorter half-life compared with sirolimus, everolimus steady-state can be reached within 4 to 6 days. The adverse event profile of everolimus is similar to that of sirolimus.

**Corticosteroids**

Traditional triple-therapy immunosuppressive regimens have consisted of a primary agent (ie, CNI, ToR inhibitor, belatacept), an antiproliferative and corticosteroids. Many renal transplant protocols have focused on corticosteroid sparing or avoidance. Avoidance or sparing of corticosteroids has been supported in the literature, although more studies are needed to help better characterize which patients should follow these protocols.

A typical taper includes a bolus of IV methylprednisolone 100 to 500 mg at the time of transplant, then tapered over days to months, depending on the type of organ, to a maintenance dose of prednisone 5 to 10 mg/day. Although most centers still use low-dose steroids for immunologically high-risk patients and nonrenal transplant patients, a number of renal transplant programs have developed an immunosuppression protocol that...
Completely withdraws corticosteroids at some point posttransplantation. Therapeutic drug monitoring of corticosteroids is not employed. Corticosteroids are associated with a variety of metabolic toxicities. The most common adverse events have been summarized in Table 55–4.

Costimulatory Pathway Blocker

Belatacept was approved in 2011 as the first IV biologic maintenance immunosuppressive agent in transplant. Belatacept blocks CD80 and CD86 ligands, found on APCs. The CD80 and CD86 proteins are responsible for stimulating CD28 on inactive T cells, an essential costimulatory interaction (Signal 2). As detailed earlier in this chapter, Signal 1 without a complementary Signal 2 induces T-cell anergy. Studies have shown that in combination with mycophenolate and corticosteroids, belatacept may be used in place of CNIs; demonstrating similar patient and allograft survival compared to a cyclosporine-based regimen. Belatacept improved renal function; however, the incidence of acute rejection was significantly higher. Belatacept was also associated with improvements in blood pressure and lipid levels.

Belatacept is available in a 250-mg vial that requires reconstitution prior to administration. The recommended dosing regimen for belatacept is 10 mg/kg on the day of transplantation, followed by an additional dose 4 days later, and again at the end of weeks 2, 4, 8, and 12, posttransplant. Beginning at the end of week 16 posttransplant, belatacept is dosed at 5 mg/kg every 4 weeks thereafter. Belatacept requires access to an infusion center/suite, or a home infusion service to ensure appropriate administration.

The most common adverse effects associated with belatacept are infectious (urinary tract infection, 37%; upper respiratory infection, 15%), GI (diarrhea, 39%; constipation, 33%; nausea, 24%, vomiting, 22%), metabolic (hyperkalemia, 20%; hypokalemia 21%), and central nervous system (CNS; headache, 21%) complications. Other adverse effects include peripheral edema, anemia, leukopenia, hypotension, arthralgia, and insomnia. Belatacept has a black-box warning for increased risk of posttransplant lymphoproliferative disorders (PTLD). Due to this risk, it is recommended that belatacept only be used in patients with a proven preexisting immunity to Epstein-Barr virus (EBV). This black-box warning has also led to the inclusion of a communication plan as part of a belatacept risk evaluation and mitigation strategy to warn practitioners that belatacept use in EBV-naïve or unequivocal patients is contraindicated. An additional black-box warning advises against use of belatacept in liver transplant patients due to an increased risk of allograft loss and patient death.

Immunosuppressive Therapies—Treatment of Acute Rejection Episodes

Acute rejection is generally treated with a course of high-dose methylprednisolone (250 to 1000 mg/day IV for 3 days), which is usually sufficient to ameliorate the episode. If the acute rejection episode is resistant to the initial course of steroids, a second course may be administered or the patient may begin therapy with r-ATG (1.5 mg/kg/day for 4 to 14 days). Cellular rejection refractory to these treatments is rare and is likely due to underlying causes such as an antibody-mediated component or other diagnosis. Treatments of refractory acute rejection may include alemtuzumab, IVIG, high-dose tacrolimus, or organ irradiation.

Immunosuppressive Therapies—Managing Highly Sensitized Patients and Antibody-Mediated Rejection Episodes

The presence of preformed antibodies, high PRA, and DSA are major barriers to successful transplantation. This is true mainly because traditional immunosuppressants do not significantly affect the humoral immune system and are ineffective at management of AMR, which is a leading cause of allograft loss in kidney and heart transplant recipients. Without some form of intervention, antibody formation and rejection can significantly impact morbidity and mortality. Two major strategies are used for reduction of DSA pretransplant: (a) high-dose IVIG and (b) plasmapheresis plus low-dose IVIG. Each approach has advantages and disadvantages.

In plasmapheresis or plasma exchange, patients’ plasma is removed and replaced with albumin or fresh-frozen plasma. Plasmapheresis produces a rapid reduction of preformed antibodies and allows transplantation to occur. The purpose of IVIG administration is to decrease anti-HLA alloantibody synthesis. The other mechanisms of IVIG are inhibition of
complement-mediated injury, reduced B-cell proliferation and NK cells, and a decrease in phagocytosis. Most patients require four to five plasmapheresis sessions with IVIG to remove DSA. In patients at risk for bleeding, the use of albumin should be limited, and fresh-frozen plasma or a combination of both agents should be considered.4

In patients who develop AMR posttransplant, there are limited therapeutic options, none of which are FDA-approved. The potential options include plasmapheresis and IVIG, rituximab, bortezomib, and/or ecfluizumab. All of these agents have an effect on humoral immunity, which may provide benefit to patients with AMR. The mechanisms of plasmapheresis and IVIG were discussed earlier in this chapter.4

Rituximab is a chimeric monoclonal anti-CD20 antibody targeting B cells.4,7 This agent directly inhibits B-cell proliferation and induces cellular apoptosis through complement-mediated antibody-dependent cellular cytotoxicity. In an analysis of AMR treatment, the use of rituximab in conjunction with plasmapheresis/IVIG resulted in improved 3-year graft survival (92% vs 50%) and significantly reduced DSA at 3 months compared with high-dose IVIG alone.29 Unfortunately, plasma cells lack CD20 and are unaffected by rituximab. However, rituximab may play an important role in reducing memory B-cell response. Overall, it appears that rituximab may provide beneficial effects in managing AMR when used in combination with other therapies.4

Bortezomib is a proteasome inhibitor indicated for treatment of multiple myeloma.4,6 It works by inducing cell-cycle arrest and apoptosis of plasma cells. Desensitization and treatment protocols using bortezomib have utilized doses of 1.3 mg/m² from one to four cycles. Acute hepatic dysfunction has rarely been reported; thus, bortezomib should be used cautiously in patients with moderate-to-severe hepatic impairment. Bortezomib has also been associated with significant myelosuppression and peripheral neuropathy. Bortezomib has been used in combination with plasmapheresis and IVIG or rituximab. The reported outcomes of these cases demonstrate graft survival rates of 85% to 100%. Anti-HLA antibodies are decreased by 50% within two weeks of therapy and remain suppressed for up to 5 months.30,31 Bortezomib also seems effective in AMR refractory to plasmapheresis and IVIG.4

Eculizumab is a humanized monoclonal antibody directed against complement protein C5.4,7 It inhibits the cleavage to C5a and C5b, thus preventing the generation of the membrane attack complex (MAC) and reducing antibody-dependent cell lysis. Eculizumab carries a FDA boxed warning of meningococcal infection. Meningococcal vaccination is recommended 14 days prior to eculizumab, but meningococcal infections have been reported even in vaccinated patients. There are only a few case reports demonstrating eculizumab’s efficacy for treating AMR, showing fast improvement of renal function observed within a week after eculizumab use.4

Maintenance Immunosuppressive Therapies—Common Drug–Drug Interactions

**KEY CONCEPT** As the number of medications a patient takes increases, so does the potential for DDIs. Disease severity, patient age, and organ dysfunction are all risk factors for DDIs. In general, DDIs are either pharmacokinetic or pharmacodynamic interactions:

- **Pharmacokinetic interactions** result when one drug alters the absorption, distribution, metabolism, or elimination of another drug.
- **Pharmacodynamic interactions** include additive, synergistic, or antagonistic interactions that can affect efficacy or toxicity.

**Pharmacokinetic Interactions**

Pharmacokinetic DDIs pose a major dilemma with the maintenance immunosuppressants. Pharmacokinetic interactions can either result in: (1) increased concentrations of one or more agents, with an increased risk for drug-induced toxicities or (2) lowered (ie, subtherapeutic) drug concentrations, possibly leading to allograft rejection. These interactions can be seen during drug absorption, distribution, metabolism, and elimination.

**Interactions of Absorption** Gut metabolism, modifications in active transport, and changes in intestinal motility and chelation interactions alter absorption of the immunosuppressants. Active transporters (ie, P-glycoprotein [P-gp]) are present in the gut, brain, liver and kidneys and play an important role in DDIs. P-gp provides a biological barrier, eliminating xenobiotics that may accumulate in these organ systems, thereby having a significant impact on the absorption and distribution of many medications. P-gp affects the absorption of the CNIs and ToR inhibitors. Medications that inhibit or induce the activity of P-gp have a significant impact on bioavailability of some of the immunosuppressive agents. For example, P-gp inhibitors, such as verapamil or quinidine, increase concentrations of cyclosporine, tacrolimus, sirolimus, and everolimus due to reduced P-gp-dependent drug elimination from the systemic circulation.7

There is a prominent interaction between the prokinetic agents and the CNIs seen through changes in intestinal motility. Metoclopramide increases the absorption of cyclosporine and tacrolimus by enhancing gastric motility and emptying, resulting in increased CNI concentrations.7

Most of the interactions with mycophenolate mofetil and enteric-coated MPA result in reductions in intestinal absorption. Proton pump inhibitors decrease the oral absorption of mycophenolate mofetil, but not enteric-coated MPA.7 Divalent and trivalent cations (ie, aluminum, magnesium, calcium) decrease MPA absorption through chelation. These agents should be administered at least 1 hour before or 2 hours after MPA. Note, iron does not appear to interact with the MPA preparations. The clinical implications of these DDIs are unknown, but reductions in MPA exposure can theoretically increase the rejection risk.

**Interactions of Distribution** Interactions of distribution occur most often with highly protein bound drugs.7 MPA is the only highly protein bound (97%) maintenance immunosuppressant with an interaction of distribution. Concomitant administration of MPA with salicylates increases MPA free concentrations. The adverse sequelae of this interaction are unknown. Drug interaction studies have not been conducted with MPA derivatives and other highly protein bound drugs.

**Interactions of Metabolism** Oxidative metabolism by cytochrome P-450 (CYP) isozymes is the primary method of xenobiotic metabolism. The CNIs and ToR inhibitors are substrates of the CYP3A isozyme system. Most CYP-mediated metabolism takes place in the liver; however, CYP is also expressed in the intestine, lungs, kidneys, and brain. Being CYP3A substrates, it would be anticipated that cyclosporine, tacrolimus, sirolimus, and everolimus would all experience similar DDI with known substrates, inhibitors, and inducers of the CYP3A isozyme system.6 Table 55–5 details the clinically relevant DDIs that occur with the calcineurin and ToR inhibitors due to inhibition or induction of the CYP3A isozyme system.7

Given how extensive some immunosuppressant DDIs are, in some cases empiric dose changes are necessitated when
Pharmacodynamic Interactions

Inhibitors

Pharmacodynamic Interactions can also be problematic, such as when medications with similar adverse events are used concomitantly. For example, nephrotoxic agents, such as amphotericin B, aminoglycosides, and nonsteroidal anti-inflammatory drugs may potentiate the nephrotoxic effects of the calcineurin inhibitors. The use of myelosuppressive agents, such as sulfamethoxazole-trimethoprim and valganciclovir, could enhance the myelosuppressive effects of induction therapy and the maintenance immunosuppressants.

In addition to reviewing prescription medications, it is essential to question patients about the use of nonprescription agents and dietary supplements, as these products also have the potential for significant interactions, through methods discussed above. Some examples of this are St. John’s wort inducing the metabolism of ciclosporine, tacrolimus, and sirolimus; therefore, proper patient monitoring is warranted.

**Pharmacodynamic Interactions**

In addition to the numerous pharmacokinetic interactions seen with the maintenance immunosuppressants, there also exists the possibility for pharmacodynamic interactions. Pharmacodynamic interactions are the backbone of modern immunosuppressive therapies that employ multiple medications with different mechanisms of action resulting in additive immunosuppression. Unfortunately, pharmacodynamic interactions can also be problematic, such as when medications with similar adverse events are used concomitantly. For example, nephrotoxic agents, such as amphotericin B, aminoglycosides, and nonsteroidal anti-inflammatory drugs may potentiate the nephrotoxic effects of the calcineurin inhibitors. The use of myelosuppressive agents, such as sulfamethoxazole-trimethoprim and valganciclovir, could enhance the myelosuppressive effects of induction therapy and the maintenance immunosuppressants.

In addition to reviewing prescription medications, it is essential to question patients about the use of nonprescription agents and dietary supplements, as these products also have the potential for significant interactions, through methods discussed above. Some examples of this are St. John’s wort inducing the metabolism of ciclosporine, tacrolimus, and sirolimus; therefore, proper patient monitoring is warranted.

Immunosuppressive Therapies—Management of Immunosuppressive Drug Complications

Opportunistic Infections

Organ transplant recipients are at increased risk of infectious diseases, which are a chief cause of early morbidity and mortality. The prevalence of posttransplant infection depends on many factors, including clinical risk factors, environmental exposures, and the degree of immunosuppression. Anti-infectives are universally prescribed in this population, and their use can be split into three different categories:

- **Prophylaxis**: antimicrobials given to prevent infection
- **Empiric**: preemptive therapy given based on clinical suspicion of an infection
- **Treatment**: antimicrobials given to manage a documented infection

Posttransplant infections generally occur in a standard pattern; therefore, prevention is a key management strategy. The information in this section is designed to highlight prophylaxis options routinely used in organ transplant recipients. Please refer to Table 55–6 for a list of agents used for the prevention of Pneumocystis jiroveci pneumonia and CMV disease.

**Pneumocystis jiroveci Pneumonia**

Without prophylaxis, P. jiroveci pneumonia occurs in 5% to 15% of transplant recipients. Antipneumocystis prophylaxis is enormously helpful and is generally used in all organ transplant recipients. The duration of prophylaxis is usually 6 to 12 months after transplant, but may be prolonged in highly immunosuppressed patients (ie, active CMV disease, treatment for rejection) or liver or

</table>
lungs. Sulfamethoxazole-trimethoprim is the preferred agent for prophylaxis. One of its major advantages is its broad spectrum of activity. Not only is it effective against *Pneumocystis*, but it also has activity against *Toxoplasma* and other common bacterial infections. Patients who have sulfa allergies, glucose-6 phosphate dehydrogenase (G6PD) deficiency, or are intolerant of sulfamethoxazole-trimethoprim should be given one of the second-line treatments. Unfortunately, the second-line agents are antiparasitics and have no meaningful activity against common bacteria. These agents include dapsone, atovaquone, and pentamidine. 

**Cytomegalovirus** CMV is a concerning opportunistic pathogen in transplantation due to its association with poor outcomes. CMV infection is present in 30% to 97% of the general population, but CMV disease is typically restricted to immunocompromised hosts. The risk of CMV disease is highest among CMV-naive recipients who receive a CMV-positive organ (donor + recipient). Other factors that augment the risk of CMV disease include organ type (lung and pancreas recipients are highest risk) and immunosuppressive agents (ALA use increases risk). CMV disease characteristically occurs within the first 3 to 6 months posttransplantation, but delayed onset disease has been seen in patients receiving antiviral prophylaxis. Patients with CMV infection may present with flu-like symptoms, including fever, chills, aches, malaise, and fatigue. CMV infection may result in more profound symptoms in the immunosuppressed patient, including leukopenia, thrombocytopenia, and organ dysfunction. 

**KEY CONCEPT** Several antivirals have proven effective in preventing and treating CMV. Valacyclovir and valganciclovir, produgs of acyclovir and ganciclovir, respectively, have improved bioavailability compared with their parent compounds and offer the advantage of less frequent dosing. CMV prophylaxis is typically continued for the first 200 days, or longer, after transplantation. Although valganciclovir and IV ganciclovir are considered the prophylaxis agents of choice in most organ transplant recipients, national guidelines allow for consideration of prophylaxis with CMV hyperimmune globulin in heart and lung transplant populations. Both IV ganciclovir and oral valganciclovir may be used for preemptive therapy or for treatment of established CMV disease. The adverse events are similar among these agents and include myelosuppression and GI effects.

**Fungal Infections** Fungal infections are an important cause of morbidity and mortality in solid organ transplant recipients. Immunologic (ie, immunosuppressants, CMV infection), anatomic (ie, tissue ischemia and damage), and surgical (ie, duration of surgery, transfusion requirements) factors contribute to the risk for invasive fungal infections. Mucocutaneous candidiasis (ie, oral thrush, esophagitis) is associated with corticosteroids and ALA. Oral nystatin or clotrimazole troches are effective prophylactic options for the prevention of thrush. However, clotrimazole inhibits the CYP3A system in the gut and can alter immunosuppressive levels. The use of systemic antifungal prophylaxis, such as oral fluconazole, is controversial due to the potential for DDI and the risk of developing resistance. The American Society of Transplantation has recommended antifungal prophylaxis in liver, lung, intestine, and pancreas transplantation. The choice of agents depends on the fungal risk in that particular population. For example, liver, intestine, and pancreas transplant recipients are at high risk for candidiasis; therefore, the use of medications that cover *Candida* spp. is crucial, such as the triazoles (ie, fluconazole, itraconazole) or echinocandins (ie, caspofungin, micafungin, anidulafungin). Lung transplant recipients are at high risk for aspergillosis; therefore, it is imperative to use antifungal prophylaxis that covers *Aspergillus* spp., such as the echinocandins, polyenes (ie, amphotericin B, lipid-based amphotericin B products) or any other drugs that have antifungal activity. 

**Polymavirus** One infection complication seen only in renal transplant recipients is polymavirus. In humans, there are two known pathologic polyoma strains, BK and JC. These viruses are rarely associated with disease in immunocompetent individuals. During periods of immunosuppression, the virus is reactivated and can be associated with significant morbidity. 

In renal transplant recipients, the major diseases caused by BK virus (BKV) are tubulointerstitial nephritis and ureteral stenosis. Polymavirus-associated nephropathy (PyVAN) presents with evidence of allograft dysfunction, resulting in either an asymptomatic acute or slowly progressive rise in serum creatinine concentrations. Some studies have reported that PyVAN may affect up to 10% of renal transplant recipients, frequently resulting in permanent renal dysfunction or allograft loss. 

Currently, treatment options for BKV are limited, and management recommendations are generally focused on reductions in immunosuppression. There is a lack of a directed antiviral intervention; however, some centers have utilized IVIG, cidofivir, lefunomide, and the fluoroquinolone antibiotics to manage BKV infections. All of these agents have been reported to provide some benefit in managing BKV in anecdotal cases. 

**Vaccination** Vaccination is one of the most effective means of preventing infection and related complications. However, there is a valid concern that solid organ transplant recipients may mount an inadequate response to vaccination due to immunosuppression. Required vaccinations should be administered prior to transplantation so that an appropriate antibody response can develop (Table 55-7). If this strategy is pursued, the earlier a vaccine is administered, the more effective it may be, as stage organ failure can also contribute to a decreased immune response. 

In general, the weakest response to vaccine is within the first 6 months posttransplantation due to the intense level of immunosuppression during this period. Vaccination within 6 months of transplant may be considered on a case-by-case basis in those patients who are at high risk of developing infection. Use of inactive vaccines is preferred in transplant recipients due to the relative risk of infection associated with live vaccines. Health care workers and family members who are in close contact with transplant patients and have received a live vaccine should consider use of respiratory masks for at least 7 days after vaccination and adhere to strict oral and hand hygiene.

**Hypertension** Cardiovascular disease has been identified as the leading cause of death in organ transplant recipients. Posttransplant hypertension is associated with increased cardiac morbidity and patient mortality in transplant patients and is also an independent risk factor for allograft dysfunction. Based on all of the available posttransplant morbidity and mortality data, it is imperative that posttransplant hypertension be identified and managed appropriately. 

There are several mechanisms responsible for posttransplant hypertension including renal dysfunction, increased sensitivity to endothelin-1 and angiotensin, increased density of glucocorticoid receptors in the vascular smooth muscle, and decreased...

- production of vasodilatory prostaglandins. However, one of the most easily recognized causes of posttransplant hypertension is the use of corticosteroids and CNIs. Corticosteroids cause sodium and water retention, thus increasing blood pressure, whereas CNIs reduce glomerular filtration rate and renal blood flow, increase systemic and intrarenal vascular resistance, promote sodium retention, reduce concentrations of systemic vasodilators (ie, prostacyclin, nitric oxide), and increase concentrations of thromboxanes. Compared with cyclosporine, tacrolimus displays significantly less severe hypertension, and patients taking tacrolimus require significantly fewer antihypertensive medications after transplant.

- **Treatment** 
  
  Controlling hypertension after transplant is essential in preventing cardiac morbidity and mortality and prolonging graft survival. The target blood pressure in transplant recipients should be less than 130/80 mm Hg. This goal blood pressure may not be suitable for all patients. Note: national guidelines for treating hypertension in the general population are often followed, despite their lack of transplant recommendations. Refer to Chapter 5, Hypertension, for additional information.

- **Lifestyle Modifications** To achieve a goal blood pressure, lifestyle modifications including diet, exercise, sodium restriction, and smoking cessation are recommended. Unfortunately, lifestyle modifications alone are often inadequate in high-risk populations, and antihypertensive medications are usually initiated early after transplant.

- **Immunosuppressive Regimen Modification** Because tacrolimus has shown the propensity to cause less severe hypertension compared to cyclosporine, conversion from cyclosporine-based immunosuppression to tacrolimus-based immunosuppression may be one way to reduce the severity of hypertension in transplant recipients. Conversion to a ToR inhibitor or belatacept, which are not associated with hypertension, may also be an alternative to the CNIs in patients with difficult-to-treat hypertension. Corticosteroid taper or withdrawal are effective strategies for lowering blood pressure, but are not warranted in all clinical situations.

- **Antihypertensive Agents** There is no single class of antihypertensive medications recognized as the ideal agent. Numerous factors must be considered when determining appropriate treatment for a patient, including the safety and efficacy data of...
available agents, patient-specific comorbidities, and medication cost.\textsuperscript{40} A large majority of patients often require multiple medications to achieve goal blood pressure, and combination therapy is regarded as an appropriate first-line therapy.\textsuperscript{40}

- **\textsuperscript{40}** β-Blockers and thiazide diuretics have proven benefits in reducing cardiovascular disease–associated morbidity and mortality.\textsuperscript{40} Tolerability permitting, these agents are to be considered first-line therapies in most transplant recipients. The angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) have definite benefits in patients with nephropathy and are believed to have renoprotective effects in most patients. However, due to their ability to cause an initial increase in serum creatinine, these agents should be used cautiously when combined with the CNIs. The dihydropyridine calcium channel blockers have demonstrated an ability to reverse nephrotoxicity associated with cyclosporine and tacrolimus. The addition of diltiazem to patients’ regimens after cardiac transplant has also been shown to retard progression of cardiac allograft vasculopathy. In general, antihypertensive therapy should focus on agents with proven benefits in reducing the progression of cardiovascular disease and must be tailored to a patient’s needs.\textsuperscript{40}

### Hyperlipidemia

**KEY CONCEPT**

Hyperlipidemia is seen in as high as 60% of transplant patients.\textsuperscript{41} As a result of elevated cholesterol levels, transplant recipients are not only at increased risk of atherosclerotic events, but also allograft vasculopathy. Hyperlipidemia, along with other types of cardiovascular disease, is now one of the primary causes of morbidity and mortality in long-term transplant survivors.\textsuperscript{41}

Elevated cholesterol levels in transplant patients are due to age, genetic disposition, renal dysfunction, DM, proteinuria, body weight, and immunosuppressive therapy. Many of the immunosuppressive agents can produce elevations in serum lipid levels.\textsuperscript{41}

**Treatment**

Lowering cholesterol has shown to significantly decrease severe rejection and transplant vasculopathy and improve 1-year survival in heart transplant recipients.\textsuperscript{42} Although these results cannot be extrapolated to other transplant populations, they do demonstrate the potential benefits of aggressive cholesterol lowering in organ transplant recipients. Due to high prevalence of cardiovascular disease among organ transplant recipients, most practitioners consider these patients to be high risk for lipid lowering. Many guidelines state a target calculated low-density lipoprotein cholesterol (LDL-C) level of less than 100 mg/dL (2.59 mmol/L) in high-risk patients.\textsuperscript{41} Note: national guidelines for treating hyperlipidemia in the general population are often followed, despite their lack of transplant recommendations. Refer to Chapter 12, Dyslipidemias, for additional information.

**Lifestyle Modifications**

Generally, lowering cholesterol in patients begins with therapeutic lifestyle changes. These changes are initiated either alone or in conjunction with lipid-lowering drug therapy, depending on baseline cholesterol levels and other risk factors. Therapeutic lifestyle changes entail a reduction in saturated fat and cholesterol intake and an increase in moderate physical activity.\textsuperscript{43} As with hypertension, lifestyle modifications alone rarely allow a patient to achieve a goal LDL-C level. Modification of the immunosuppressive regimen and use of cholesterol-lowering medications are often warranted in this population.\textsuperscript{44}

**Immunosuppressive Regimen Modifications**

Tacrolimus has shown the propensity to cause less severe hyperlipidemia when compared with cyclosporine. Conversion from cyclosporine-based immunosuppression to tacrolimus-based immunosuppression may be one way to counteract this disease in transplant recipients. Also, the ToR inhibitors have been associated with significant changes in lipids and triglycerides; therefore, conversion from a ToR inhibitor to a CNI or belatacept may be warranted in patients receiving ToR inhibitor therapy with resistant dyslipidemia.\textsuperscript{41}

In past studies, steroid withdrawal in renal transplant patients did demonstrate moderate reductions in total cholesterol and LDL cholesterol; unfortunately, a decrease in high-density lipoprotein (HDL) levels were also noted.\textsuperscript{41}

**Cholesterol-Lowering Agents**

- **3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, or statins, are considered first-line therapy for hyperlipidemia in the general population.**\textsuperscript{41} However, there is some uncertainty about the pathogenesis of cardiovascular disease in transplant recipients and whether statin therapy will have similar effectiveness in organ transplant recipients. Statins have shown definite advantages when used in heart transplantation, including a reduction in LDL-C and major adverse cardiac events (MACE), as well as an apparent cardioprotective effect. In renal transplant recipients, statins lower LDL-C levels and reduce the incidence of some cardiac events; however, the ability to lower MACE has not been seen in this population. Despite these mixed results, statins are still considered the primary therapeutic option for hyperlipidemia in organ transplant recipients.\textsuperscript{41} When choosing a statin for management of hyperlipidemia in the transplant patient, a focus on potential DDIs is warranted. It is recommended that doses of atorvastatin not exceed 10 mg daily when taken with cyclosporine due to an increased risk of myopathy and rhabdomyolysis. Use of cyclosporine in conjunction with simvastatin is considered a contraindication due to the risk of skeletal muscle effects.\textsuperscript{41}

- **Fibric acid derivatives are an excellent choice for lowering triglycerides, but are not as effective as statins at lowering LDL-C.**\textsuperscript{41} These agents play a role in conjunction with statins in patients with both elevated cholesterol and triglycerides. Nicotinic acid is very effective at improving the lipid panel, with excellent results in lowering LDL-C, as well as increasing HDL. However, patient tolerability is a concern with this agent. The bile acid sequestrants should be avoided in transplant recipients due to their high incidence of GI adverse events, as well as their propensity for pharmacokinetic DDIs with MPA. Ezetimibe has proven safe and effective in lowering LDL-C in renal transplant recipients. Future studies are needed to establish ideal regimens involving the antihyperlipidemic and immunosuppressive medications to decrease morbidity and mortality and ultimately prevent cardiovascular events.\textsuperscript{41}

**New-Onset DM After Transplantation**

**KEY CONCEPT**

New-onset DM after transplantation (NODAT) is a serious complication that is often underestimated by transplant practitioners.\textsuperscript{44} Kasiski and colleagues attempted to quantify the cumulative incidence of NODAT in renal transplant recipients and found that 8.3% of patients developed NODAT at 3 months posttransplant, 12.9% at 12 months, and 22.3% at 36 months.\textsuperscript{45} Even more alarming is that recent studies have revealed an overwhelming prevalence of impaired glucose tolerance, which is also accepted as a risk factor for long-term morbidity and mortality. NODAT is associated with a 22% higher risk of mortality. Patients with NODAT are also more likely to suffer acute rejection episodes and infectious complications than patients without NODAT.\textsuperscript{44}
**Prevention**  
NODAT prevention mainly consists of identifying patients at risk before transplant and controlling modifiable risk factors both before and after transplantation. The major modifiable risk factors are choice of immunosuppressive therapy and body mass index (BMI). For example:

- Immunosuppressive medications: Steroid minimization and possibly withdrawal are effective strategies for preventing NODAT. Also, patients with worsening blood glucose who are receiving tacrolimus may benefit from conversion to cyclosporine or belatacept.  
- Body mass index: A reduction in body weight is recommended in obese patients prior to transplant to lower their NODAT risks.

**Treatment**  
Lifestyle modifications are recommended in patients who have developed or those who are at increased risk of developing NODAT. Insulin therapy and oral hypoglycemic agents are often utilized in those patients in whom lifestyle modifications alone have not controlled blood glucose. Please refer to Chapter 43, *Diabetes Mellitus*, for proper instruction on choosing the appropriate treatment regimens in patients with DM.

### Neoplasia

**Cancer Screening in Transplant Patients**  
Transplant recipients are at increased risk for malignancies (Table 55–8). The risk of developing Kaposi sarcoma following transplantation is over 200 times that in the general population. In addition, the risk of nonmelanocytic and melanocytic skin cancer is 10 to 20 times higher compared with the nontransplanted population. Transplant recipients are at greatest risk for the types of cancers associated with viral infections, such as PTLD, cervical, and vulvovaginal cancers. Solid organ tumors like colorectal and lung cancers are two to three times higher in transplant recipients when compared with the general population. The American Cancer Society and American Transplant Society recommend cancer screening for most adults who have undergone transplantation (Table 55–9). Although clinical research has not yet proven that potential benefits of testing outweigh the harms of testing in transplant recipients, most believe that transplant recipients should be tested and screened very closely.

**Skin Cancer**  
Skin cancer remains the most common malignancy after transplantation. The incidence of these types of cancers increases with time posttransplant, with one study showing a prevalence rate of 35% among patients within 10 years after transplant. Also, skin cancers in transplant recipients tend to grow more rapidly and are more likely to metastasize.

The most common risk factors for skin cancer development after transplant include increased age; excessive ultraviolet (UV) light exposure; high degree of immunosuppression; Fitzpatrick skin types I, II, and III; history of skin cancers; and infection by human papillomavirus. Many believe that ToR inhibitors in place of CNIs in transplant recipients can reduce the risk of nonmelanoma skin carcinomas.

Transplant practitioners must be vigilant about educating their patients about excessive exposure to the sun. Patients should be warned about the risk of skin cancer and be advised on simple methods to limit risk:

- Wear protective clothing (ie, long-sleeved shirts, pants, dark-colored clothing)
- Use of sunscreen, sun protection factor (SPF) 30 or higher, daily to all sun-exposed skin

**Posttransplant Lymphoproliferative Disorders**  
PTLDs are a major complication following organ transplantation. Large series of case reports have demonstrated the incidence of PTLD is 1% for renal patients, 1.8% for cardiac patients, 2.2% for liver patients, and 9.4% for heart–lung patients. The risk of developing non–Hodgkin lymphoma is nearly 50-fold higher in organ transplant recipients compared with the general population. Another risk factor is the presence of EBV. Lymphomas are the most common form of PTLD.

The incidence of disease depends on certain factors that include the type of organ transplanted, age of the transplant recipient, type and degree of immunosuppression, and exposure to EBV. The mortality rate in these patients is 50%, with most patients dying shortly after diagnosis. It has also been demonstrated that the risk of developing PTLD is greater in EBV seronegative patients. Belatacept has been approved with a black box warning outlining an increased risk of PTLD, especially of the CNS. Patients who are EBV seronegative or have an unknown immunity to EBV should not receive belatacept. Also, immunosuppressive regimens utilizing the ALAs have been proven to increase the risk of PTLD.

**Treatment**  
Treatment for PTLD is still controversial; however, the most common treatment options include reduction of immunosuppression, chemotherapy, and anti–B cell monoclonal antibodies. PTLD continues to be a long-term complication of prolonged immunosuppression. Current treatment options are all associated with certain risks. Prevention is the most effective treatment for PTLD. A better understanding of the disease process and the risk factors involved with the development of PTLD will aid in the prophylaxis and treatment of this disorder.

**Pregnancy**  
Females of childbearing age who do not wish to become pregnant after transplantation require adequate education on preferred forms of birth control. The optimal method of birth control in this patient population is the barrier method (eg condom, diaphragm). Use of intrauterine devices and progestin-based oral contraceptives are controversial, and associated risks must be considered prior to initiating therapy. Intrauterine devices may be less effective in the setting of immunosuppression and...
predispose patients to an increased risk of infection. Progestin-based contraceptives are considered a less effective form of birth control, but may be a safe option in those patients without hypertension.49

Female patients considering pregnancy after transplantation should be educated extensively regarding the potential impact of pregnancy on renal function and the risks that transplantation and medical immunosuppression may present to a fetus.49 Risks to the infant include premature birth (50%) and intrauterine growth restriction (20%), which may result in death or long-term complications, including cerebral palsy, blindness, deafness, and learning deficiencies. Patients hoping to become pregnant should wait at least 1 year after transplantation to ensure reconstitution of gonadal function posttransplant, as well as demonstrate a 1-year freedom from acute rejection.49

Understanding the associated risk of immunosuppressives while pregnant is paramount considering their ability to cross the placenta as well as enter breast milk.49 Tacrolimus and cyclosporine, both Pregnancy Category C, are the backbone of immunosuppressive therapy and have been used safely and effectively in pregnancy posttransplant for decades. Side effects associated with CNIs such as hypertension, diabetes, and nephrotoxicity should be monitored closely in the pregnant population. The ToR inhibitors are also Pregnancy Category C and have not been associated with fetal malformation but should be used cautiously in pregnant patients. Corticosteroids, pregnancy category B, are recognized to be relatively safe and have been used extensively in pregnancy after transplantation. However, they carry a risk of premature membrane rupture and newborn adrenal insufficiency. More common side effects associated with corticosteroids that may cause complications in pregnancy include hypertension, diabetes, weight gain, and poor wound healing. Due to teratogenic effects in animal studies, azathioprine is considered Pregnancy Category D; however, it has been used extensively as an antimetabolite in pregnant transplant patients without extensive evidence of harm to the fetus. 6-Mercaptopurine has not been shown to cross the placental barrier.49

Currently, the MPA derivatives, both Pregnancy Category D, are not considered optimal immunosuppressive agents for patients who become pregnant, and alternative therapies should be pursued.49 These agents have a FDA-approved risk evaluation and minimization strategy to help minimize fetal exposure to MPA, prevent unplanned pregnancies in patients using MPA, collect data on MPA use in pregnancy via the Mycophenolate Pregnancy Registry, and educate patients about the risks associated with the use of this medication. A less teratogenic antimetabolite, azathioprine, should be substituted for mycophenolate mofetil or enteric-coated MPA in patients who plan on becoming pregnant. The safety of ALAs and rituximab in pregnancy has yet to be fully determined; however, IVIG has been widely used without any documented adverse events. Newly available immunosuppressives, belatacept and everolimus, are pregnancy category C but are not recommended for use in pregnant patients due to inadequate human data.49

**Immunosuppressant Therapy Adherence**

Transplant recipients require strict adherence to their medication regimens to ensure optimal outcomes. Nonadherence

**Patient Care Process**

**Early Management of Transplant Recipients**

**Patient Assessment:**
- Review all available diagnostic and laboratory data, and patient history and comorbidities to evaluate patient as a transplant recipient.

**Therapy Evaluation:**
- Evaluate medications currently being used by patient that will be continued posttransplant such as drugs to treat concomitant disease states (eg, hypertension, DM, dyslipidemia).
- For medications that are likely to be continued posttransplant, assess efficacy, safety, and patient adherence. Are there any significant drug interactions?

**Care Plan Development:**
- Propose an immunosuppressive regimen following transplantation, including:
  - Induction therapy (see Table 55–2):
    - Based on the type of organ being transplanted, recipient’s history and donor characteristics, determine if the patient requires induction therapy.
    - If you decide to use induction therapy, assess for appropriate drug choice, dose, and duration of therapy.
  - Maintenance immunosuppressive agents (see Tables 55–2, 55–3, 55–4, and 55–5, and Figure 55–2):
    - Assess for appropriate choice, dose, and duration of therapy.
  - Antimicrobial prophylaxis (see Table 55–6):
    - Assess suitability of chosen prophylactic agents (eg, drug allergies, CMV donor and recipient serostatus, need for antifungal prophylaxis).
- Medications used for comorbidities:
  - Assess appropriate selection of these medications for pharmacokinetic and pharmacodynamic DDIs, need, efficacy, and side effects.
  - Determine if patient has insurance coverage and what agents are on formulary.
  - Develop patient-specific short-term and long-term therapeutic goals.
  - Provide patient education regarding the organ transplant, complications associated with transplantation, need for lifestyle modifications to reduce risk of complications (eg, wear sunscreen, low-sodium diet), and drug therapy (including importance of adherence to therapeutic regimen and insurance/payer information).
  - Assess the need for therapeutic drug monitoring of any of the immunosuppressants.
  - General therapeutic monitoring parameters based on organ transplanted and toxic monitoring parameters for medications prescribed.
  - Continually evaluate the patient for presence of adverse drug reactions, drug allergies, or DDIs.

**Follow-Up Evaluation (Outpatient Transplant Clinic):**
- Obtain a thorough history of prescription, nonprescription, and complementary and alternative medication use.
- Monitor the patient’s maintenance immunosuppression.
  - Assess for appropriate dose and duration of therapy.
  - Assess for new or worsening disease states such as hypertension, DM, or dyslipidemia.
  - Antimicrobial prophylaxis:
    - Does the patient need continued prophylaxis therapy?
    - When do you stop prophylaxis?

(Continued)
Patient Care Process (Continued)

- Medications used for comorbidities:
  - Assess appropriate selection of these medications for pharmacokinetic and pharmacodynamic DDIs, need, and efficacy.
  - Assess whether new medications are needed for existing comorbidities or new diagnoses.
  - Reassess your patient-specific short-term and long-term therapeutic goals.

- Continue with patient education in regard to the complications associated with transplantation, the need for lifestyle modifications to reduce risk of complications (eg, wear sunscreen, low-sodium diet), and drug therapy.
- Reemphasize the importance of adherence with therapeutic regimen.
- Assess improvement in quality-of-life measures such as physical, psychological, and social functioning, and well-being.

**OUTCOME EVALUATION**

- Successful outcomes in solid organ transplantation are generally measured in terms of several separate end points: (a) preventing rejection, (b) preventing immunosuppressive drug complications, and (c) improving long-term survival.

- The short-term goals revolve around reducing the incidence of acute rejection episodes and attaining a high graft survival rate. By accomplishing these goals, transplant clinicians hope to attain good allograft function to allow for an improved quality of life. These goals can be achieved through the appropriate use of medical immunosuppression and scrutinizing over the therapeutic and toxic monitoring parameters associated with each medication employed. In addition, transplant recipients should be monitored for adverse drug reactions, DDIs, and adherence with their therapeutic regimen.

- The long-term goals after organ transplant are to maximize the functionality of the allograft and prevent the complications of immunosuppression, which lead to improved patient survival. Clinicians must play multiple roles in the long-term care of transplant recipients, as not only must the patient be followed from an immunologic perspective, but practitioners must be focused on identifying and treating the adverse sequelae associated with lifelong immunosuppression including cardiovascular disease, malignancy, infection, and osteoporosis, among others. Again, limiting drug misadventures and ensuring adherence with the therapeutic regimen are important and should be stressed.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the association between osteoporosis and morbidity and mortality.
2. Identify risk factors that predispose patients to osteoporosis.
3. Describe the pathogenesis of fractures.
4. List the criteria for diagnosis of osteoporosis.
5. Recommend appropriate lifestyle modifications to prevent bone loss.
6. Compare and contrast the effect of available treatment options on reduction of fracture risk.
7. Recommend an appropriate treatment regimen for a patient with osteoporosis and develop a monitoring plan for the selected regimen.
8. Educate patients on osteoporosis and drug treatment, including appropriate use, administration, and adverse effects.

INTRODUCTION

Osteoporosis is a common and often silent disorder causing significant morbidity and mortality and reduced quality of life. It is characterized by low bone density and loss of strength in bone tissue resulting in an increased risk and rate of bone fracture. Osteoporosis is responsible for more than 2 million fractures in the United States annually. Almost 10 million Americans have osteoporosis, and an additional 43 million are classified as having low bone density. The cost of care is expected to rise to $25.3 billion by 2025. It is estimated that postmenopausal white women have a 50% lifetime chance of developing an osteoporosis-related fracture, whereas men have a 20% lifetime chance. Common sites of fracture include the spine, hip, and wrist, although almost all sites can be affected.

The fractures associated with osteoporosis have an enormous impact on individual patients, not only causing initial pain, but also chronic pain, loss of mobility, depression, nursing home placement, and death. Patients with vertebral fractures may also experience height loss, kyphosis, and decreased mobility due to limitations in bending and reaching. These patients are also at greater risk of having a future vertebral fracture. Multiple vertebral fractures may lead to restrictive lung disease and altered abdominal anatomy, while patients with hip fractures have added risks associated with surgical intervention to repair the fracture. More than 50% of patients never fully recover or regain preinjury independence. Death is common in the year after a hip fracture.

EPIDEMIOLOGY AND ETIOLOGY

Osteoporosis is the most common skeletal disorder, but only one in three patients with osteoporosis are diagnosed, and only one in seven receives treatment. Osteoporosis can be classified as either primary (no known cause) or secondary (caused by drugs or other diseases). Primary osteoporosis is most often found in postmenopausal women and aging men, but it can occur in other age groups as well.

The prevalence of osteoporosis varies by age, gender, and race/ethnicity and increases exponentially after age 50. Most hip fractures occur in postmenopausal white women, who also have the highest incidence of fracture when adjusted for age. The frequency of fracture in African American and Hispanic women trail far behind that of Caucasians, although hip fracture-related mortality may be higher. Although both men and women lose bone as they age, postmenopausal women have accelerated bone loss due to loss of estrogen. Men have some protection from osteoporosis due to their larger initial bone mass and size and lack of accelerated bone loss associated with menopause. Secondary causes of osteoporosis, such as hypogonadism, are found more commonly in men with fragility fractures.

PATHOPHYSIOLOGY

The human skeleton contains both cortical and trabecular bone. Cortical bone comprises approximately 80% of the skeleton, and its density and compactness account for much of bone strength. It is generally found on the surfaces of long and flat bones. Trabecular (or cancellous) bone has a sponge-like appearance and is found along the inner surfaces of long bones and throughout the vertebrae, pelvis, and ribs.

Under normal circumstances, the skeleton undergoes a dynamic process of bone remodeling, responding to stress and injury through continuous replacement and repair. This process is completed by the basic multicellular unit, including both osteoblasts and osteoclasts. Osteoclasts are involved...
with resorption or breakdown of bone and continuously create microscopic cavities in bone tissue. Osteoblasts are involved in bone formation and continuously mineralize new bone in the cavities created by osteoclasts. Until peak bone mass is achieved between the ages of 25 and 35, bone formation exceeds bone resorption for an overall increase in bone mass. Trabecular bone is more susceptible to bone remodeling, and therefore osteoporotic fractures, in part due to its larger surface area. Figure 56–1 illustrates the difference between normal and osteoporotic bone.

In osteoporosis, an imbalance in bone remodeling occurs. Most commonly, osteoclastic activity is enhanced, resulting in overall bone loss. However, a reduction in osteoblastic activity and bone formation also occurs in certain types of osteoporosis. Due to a decrease in endogenous estrogen, bone remodeling accelerates during menopause, and up to 15% of bone is lost during the first 5 years postmenopause. After this initial decline, bone loss continues to occur at a slower rate of up to 1% per year. The resultant bone loss and change in bone quality predispose patients to low-impact or fragility fractures.

CLINICAL PRESENTATION AND DIAGNOSIS

See accompanying text box for the clinical presentation of osteoporosis.

### Clinical Presentation of Osteoporosis

**General**

Many patients with osteoporosis are asymptomatic unless they experience a fragility fracture.

**Symptoms of Fragility Fracture**

Pain at the site of the fracture or immobility.

**Signs**

Height loss (greater than 2 cm), spinal kyphosis (“dowager’s hump”), fragility fracture especially of the hip or spine.

<sup>a</sup>Major risk factors used in the World Health Organization (WHO) fracture risk model.

<sup>b</sup>Secondary causes included in the FRAX tool question are type 1 diabetes, osteogenesis imperfecta as an adult, longstanding untreated hyperthyroidism, hypogonadism, premature menopause (before 45 years of age), chronic malnutrition, malabsorption, and chronic liver disease.

### The National Osteoporosis Foundation (NOF) recommends evaluating all postmenopausal women and men older than 50 years for osteoporosis risk and need for further diagnostic assessment.

Many risk factors for osteoporosis and osteoporotic fractures are predictors of low bone mineral density (BMD), such as age and ethnicity (Table 56–1). The risk for osteoporosis generally increases as the number of risk factors increases, and the risk of fractures increases as BMD decreases. However, the threshold at which individual patients develop a fracture varies, and other factors, such as fall risk, may play a role in fracture susceptibility. For this reason, fall history and evaluation of risk factors for falling should also be included in the initial evaluation. Because osteoporosis is commonly caused by secondary factors (Table 56–2), medical history, medication history, and laboratory values should be evaluated to determine if further work-up is needed.

### Diagnostic Assessment

The diagnostic assessment for osteoporosis may include an assessment of BMD, vertebral imaging, laboratory work-up, and other factors for secondary causes of osteoporosis, and
Measurement of Bone Mineral Density

Osteoporosis is characterized by weakened bone tissue, and BMD is the best measure of bone strength, representing approximately 70% of bone strength. Low BMD is associated with an increased risk of fractures. BMD can be measured at various sites throughout the skeletal system and by various methods. Dual-energy x-ray absorptiometry (DXA) can be used to measure central (hip and/or spine) and peripheral (heel, forearm, or hand) sites. Quantitative ultrasound, peripheral quantitative computed tomography, radiographic absorptiometry, and single-energy x-ray absorptiometry are used to measure peripheral sites.

The World Health Organization (WHO) recommends a standardized approach to measuring BMD for diagnosis of osteoporosis using central measurement of BMD by DXA. Preferred sites for central measurement include the total hip, femoral neck, and lumbar spine. Some instruments used for peripheral bone densitometry are portable, allowing bone density to be measured in pharmacies and health-fair screening booths. In addition to accessibility, peripheral measurement of BMD is generally less expensive than central DXA, making it an attractive option for many patients. Peripheral BMD testing is useful in identifying patients who are candidates for central DXA and who are at increased risk of fracture, but it should not be used for diagnosis.

Once the BMD report is available, T-scores and Z-scores are used to interpret the data. The T-score is the number of standard deviations from the mean BMD in healthy, young, white women. Osteoporosis is defined as a T-score at least –2.5 standard deviations below the mean BMD in young adults (Table 56–3). Osteopenia, or low bone mass that may eventually lead to osteoporosis, is defined as a T-score between –2.5 and –1.0. The Z-score, defined as the number of standard deviations from the mean BMD of age- and sex-matched controls, is similar to the T-score but is corrected for both age and sex of the patient. Z-scores may be more clinically relevant in evaluating BMD in premenopausal women, men younger than the age of 50, and patients who may have secondary causes for low BMD.

Screening and Risk Factor Assessment

The NOF recommends BMD measurements in the following groups: women age 65 and older, men age 70 and older, perimenopausal women and men age 50 to 69 with risk factors, anyone with a fracture after age 50, and adults with a secondary cause for osteoporosis.

FRAX (see www.shef.ac.uk/FRAX) is an additional tool developed by the WHO to evaluate an individual’s 10-year probability of developing hip and major osteoporotic fractures based on femoral neck BMD T-score, age, and other risk factors. Its intended use is for men and women older than 40 years. The FRAX tool has not been validated for patients with previous or current use of pharmacotherapy to treat osteoporosis. Although the T-score is helpful in calculating risk of fracture with FRAX, fracture risk may be calculated without it.

Vertebral Imaging

Vertebral fractures cause significant morbidity and mortality among patients with osteoporosis. They are often clinically silent, widespread, frequently recur, and commonly go undiagnosed. For these reasons, vertebral imaging is recommended in high-risk patients: central T-score less than –1.0 in women age 70 and older and men age 80 and older; central T-score less than –1.5 in women age 65 to 69 or men age 70 to 79; and postmenopausal women and men age 50 and older who have had a fragility fracture in adulthood, height loss of 4 or more centimeters from adulthood, prospective height loss of 2 or more centimeters, or long-term glucocorticoid therapy. Patients may receive vertebral imaging through traditional x-ray or lateral vertebral fracture assessment available on some DXA machines.

Laboratory Evaluation

Laboratory assessment has little value in diagnosing osteoporosis but can be beneficial in identifying or excluding secondary causes of bone loss, or predicting patients who may be at risk for more rapid bone loss or fractures. Screening laboratory tests for the most common causes of secondary osteoporosis include complete blood cell count, serum chemistries (electrolytes with
Patient Encounter, Part 1: Patient History

HPI: A frail 71-year-old white man presents to the clinic for follow-up. He reports occasional forgetfulness. His erectile dysfunction, poor libido, and fatigue have improved since starting testosterone replacement therapy. He has no complaints with his current medication regimen for COPD. He takes calcium carbonate (Tums) approximately once a week for heartburn after eating spicy meals. He usually spends his day inside the house watching television from his recliner. He states that milk upsets his stomach, so he usually drinks black coffee or diet soda, occasionally fruit juice.

PMH: COPD, DM type 2, HTN, hyperlipidemia, GERD, hypogonadism, lactose intolerance

FH: Father died at age 76 with Alzheimer disease; mother died at age 92 with history of breast cancer and osteoporotic fracture of the hip; sister alive and well at age 69

SH: Retired construction worker; drinks four beers per day; smoked two packs a day for 40 years, now two cigars daily

Meds: Albuterol inhaler two puffs as needed, metformin 500 mg twice daily; lisinopril 10 mg daily; atorvastatin 40 mg daily, omeprazole 20 mg daily; calcium carbonate (Tums) 500 mg as needed; testosterone cypionate 200 mg IM every 2 weeks; tiotropium 18 mcg daily

Do any symptoms suggest the presence of osteoporosis?

What risk factors for osteoporosis does this patient have as defined by the World Health Organization?

What diseases or medications could contribute to osteoporosis in this patient?

What are the recommended daily intakes for calcium and vitamin D?

How could he incorporate more calcium into his diet?

calcium, phosphorus and liver enzymes), vitamin D, and urinalysis. Biochemical markers of bone turnover such as pyridoline, deoxypyridinoline, N-telopeptides, and C-telopeptides are not intended for widespread clinical use due to variability and limited clinical data but may be beneficial in some patients to monitor response to therapy, medication adherence, or drug absorption.

TREATMENT

Desired Outcomes

**KEY CONCEPT** Treatment goals for osteoporosis include: (a) preventing fractures and their complications; (b) maintaining or increasing BMD; (c) preventing secondary causes of bone loss; and (d) reducing morbidity and mortality associated with osteoporosis. Strategies to prevent fractures include maximizing peak bone mass, reducing bone loss, and using precautions to prevent falls leading to fragility fractures.

Nonpharmacologic Therapy

**Modification of Risk Factors**

Some osteoporosis risk factors (see Tables 56–1 and 56–2) are nonmodifiable, including family history, age, ethnicity, gender, and concomitant disease states. However, certain risk factors for bone loss may be minimized by early intervention, including smoking, low calcium intake, poor nutrition, inactivity, heavy alcohol use, and vitamin D deficiency. To avoid certain risk factors and maximize peak bone mass, efforts must be directed toward osteoporosis prevention at an early age.

**Nutrition**

A healthy diet is essential to ensure sufficient nutrient intake and appropriate weight maintenance. Dietary calcium intake is important for achieving peak bone mass and maintaining bone density. Good dietary sources of calcium include dairy products, fortified juice, cruciferous vegetables (eg, broccoli, kale), salmon, and sardines (Table 56–4). Dietary intake generally provides 600 to 700 mg/day of calcium for men and women 50 and older. Supplementation to achieve recommended intake not attained by diet alone is important for primary prevention, as well as for those with a diagnosis of osteoporosis.

Adequate dietary intake of vitamin D is essential for calcium absorption. The most common source of vitamin D comes from exposure to sunlight. Ultraviolet rays from the sun promote synthesis of vitamin D3 (cholecalciferol) in the skin, generally occurring within 15 minutes of direct sunlight exposure to exposed skin without sunscreen. However, during the winter months, patients living in northern latitudes are not able to obtain the type of exposure that results in vitamin D synthesis. It is recommended that individuals receive twice weekly sun exposure to ensure optimal synthesis. Vitamin D may also be found in some dietary sources, including fortified milk, egg yolks, salt-water fish, and liver.

**Exercise**

Exercise can help prevent fragility fractures. Weight-bearing exercise such as walking, jogging, dancing, and climbing stairs can help build and maintain bone strength. Muscle-strengthening or resistance exercises can help improve and maintain strength, agility, and balance, which can reduce falls. It is

One tablespoon is equivalent to approximately 15 mL.
important to develop and maintain a lifelong routine of weight-bearing and resistance exercise, because the benefits on bone can be lost after cessation of the exercise program.\textsuperscript{1}

► Falls Prevention

Another crucial step in avoiding fragility fractures is prevention of falls. Patients with frailty, poor vision, hearing loss, or those taking medications affecting balance are at higher risk for falling and subsequent fragility fractures.\textsuperscript{1,2}

A number of medications have been associated with an increased risk of falling, including drugs affecting mental status such as antipsychotics, benzodiazepines, tricyclic antidepressants, sedative/hypnotics, anticholinergics, and corticosteroids. Some cardiovascular and antihypertensive drugs can also contribute to falls, especially those causing orthostatic hypotension.\textsuperscript{1} Efforts to decrease the risk of falling include balance training, muscle strengthening, removal of hazards in the home, installation of fall reduction measures such as handrails, and discontinuation of predisposing medications.\textsuperscript{1,2}

Pharmacologic Treatment (Figure 56–2)

**KEY CONCEPT** The NOF recommends that all men and women older than 50 years be considered for pharmacologic treatment if they meet any of the following criteria: (a) history of hip or vertebral fracture, (b) T-score \(-2.5\) or less at femoral neck or spine, or (c) osteopenia and at least a 3\% 10-year probability of hip fracture or at least a 20\% 10-year probability of major osteoporosis-related fracture as determined by FRAX.\textsuperscript{1}

► Calcium and Vitamin D

**KEY CONCEPT** Calcium and vitamin D supplements to meet requirements should be added to all drug therapy regimens for osteoporosis to increase BMD and decrease the risk of hip and vertebral fractures.

Calcium plays an important role in maximizing peak bone mass and decreasing bone turnover, thereby slowing bone loss. When the calcium supply is insufficient, calcium is taken from bone stores to maintain the serum calcium level. Adequate calcium consumption is essential to prevent this from occurring and may also correct secondary hyperparathyroidism in elderly patients.

The NOF recommends a daily calcium intake of 1000 mg for men between the ages of 50 to 70 and a higher intake of 1200 mg for women older than 51 and men older than 71.\textsuperscript{1} When these requirements cannot be achieved by diet alone, appropriate calcium supplementation is recommended. Intakes over 1200 to 1500 mg/day may increase the risk of developing kidney stones,\textsuperscript{1} and supplementation greater than 2500 mg/day may lead to hypercalciuria and hypercalcemia. Additionally, excessive calcium supplementation may be associated with an increased risk of cardiovascular events.\textsuperscript{1,9}

Calcium supplements are available in a variety of calcium salts and dosage forms. Daily calcium requirements are reported as elemental calcium. However, many product labels list calcium content in the salt form, so the percentage of elemental calcium must be known to calculate the elemental calcium content per tablet. A number of factors, including a single large intake of calcium, can limit calcium absorption, and special consideration must be given to calcium dosing to maximize absorption. Supplement doses should be limited to 500 to 600 mg of elemental calcium per dose, and absorption parameters, elemental calcium content, and adherence should be considered when choosing an appropriate supplement (Table 56–5).

Calcium carbonate should be taken with food to maximize absorption. Elderly patients or patients receiving proton pump inhibitors or H\textsubscript{2}-receptor antagonists may have difficulty absorbing calcium supplements due to reduced stomach acidity. Calcium citrate may be better absorbed in these situations because an acid environment is not needed for absorption; it may be taken with or without food.

Common adverse effects of calcium salts include constipation, bloating, cramps, and flatulence. Changing to a different salt form may alleviate symptoms for some patients. Calcium salts may reduce the absorption of iron and some antibiotics, such as tetracycline and fluoroquinolones.

Vitamin D is crucial for calcium absorption and maintenance of bone. The goal is to maintain a serum 25-hydroxyvitamin D level above 30 ng/mL (75 nmol/L).\textsuperscript{1} The NOF recommends a daily vitamin D intake of 800 to 1000 IU daily for all adults age 50 and older. However, higher doses may be necessary in some patients to meet this goal.

Vitamin D is available as a single entity, in combination with varying amounts of calcium salts, and in many multivitamin preparations. To avoid hypercalciauria and hypercalcemia, the maximum recommended dose for chronic use in most patients is 4000 IU/day.\textsuperscript{1} High-dose ergocalciferol (vitamin D\textsubscript{2}) is available by prescription only and is generally reserved for patients with vitamin D deficiency, whereas cholecalciferol (vitamin D\textsubscript{3}) is available over the counter.

Patients at risk for vitamin D deficiency include elderly patients with malabsorption syndromes, chronic renal insufficiency, other chronic diseases, and those with limited sun exposure.\textsuperscript{1} Elderly patients in particular are at increased risk of deficiency due to decreased exposure to sunlight and subsequent decreased vitamin D synthesis in the skin, decreased GI absorption of vitamin D, and reduction in vitamin D synthesis.

Many adults have low vitamin D levels, and vitamin D deficiency is an important secondary cause of osteoporosis.\textsuperscript{2,12} Laboratory determination of 25-hydroxyvitamin D levels should occur prior to the start of therapy to determine whether supplementation is adequate or whether treatment of deficiency is needed. The Endocrine Society Vitamin D Deficiency clinical practice guideline recommends treatment with ergocalciferol 50,000 IU once weekly (or cholecalciferol equivalent of 6000 IU daily) for 8 to 12 weeks.\textsuperscript{18} After 25-hydroxyvitamin D levels have risen above 30 ng/mL (75 nmol/L), cholecalciferol doses of 1500 to 2000 IU can be used to maintain 25-hydroxyvitamin D levels between 30 and 60 ng/mL (75 and 150 nmol/L).\textsuperscript{2,10}

► Bisphosphonates

**KEY CONCEPT** Bisphosphonates are first-line therapy for osteoporosis in both men and women due to established efficacy in preventing hip and vertebral fractures. They decrease bone resorption by binding to the bone matrix and inhibiting osteoclast activity. They remain in the bone for several years and are released very slowly, thereby increasing BMD. Alendronate, ibandronate, risedronate, and zoledronic acid carry an FDA-approved indication for osteoporosis. All of these agents are approved for use in men and women, with the exception of ibandronate, which is only approved for use in postmenopausal osteoporosis. Ibandronate is generally considered a second-line bisphosphonate due to lack of documented efficacy in nonvertebral fractures in prospective trials.\textsuperscript{2,11} Table 56–6 contains comparative dosing and cost information for the bisphosphonates.

Bisphosphonates can increase BMD by up to 5\% to 8\% in the lumbar spine and up to 3\% to 6\% in the hip.\textsuperscript{12,13} BMD continues
Men and women age 50 years and older

- Presence of a low trauma fracture (vertebrae, hip)?

  - Evaluation for secondary causes
  - Bone healthy lifestyle:
    - Women older than 50 years and men older than 70 years:
      - Calcium 1200 mg/day
      - Vitamin D 800 – 1000 IU/day
    - Men 50 to 70: Calcium 1000 mg/day
      - Vitamin D 800–1000 IU/day
  - Drug therapy:
    - 1st line: 1a: Bisphosphonate
      - 1b: Denosumab
    - 2nd line: Teriparatide or raloxifene
    - 3rd line: Intranasal calcitonin

Meet criteria for BMD Assessment?

- Women 65 years of age or older and men 70 years of age or older
- Women younger than 65 or men age 50–69 with risk factors for fracture
- Abnormal peripheral BMD test
- Radiographic evidence of osteopenia
- Medical conditions or medications known to increase the risk for bone loss and fracture (e.g., rheumatoid arthritis)

Send for central DXA testing

- T-score –1.0 or greater
- T-score –1.0 to –2.5 AND FRAX 10-year risk:
  - Less than 3% hip
  - Less than 20% major osteoporotic

- T-score less than –2.5 OR T-score –1.0 to –2.5 AND FRAX 10-year risk:
  - 3% or greater hip
  - 20% or greater major osteoporotic

- Investigate for a secondary cause and treat as appropriate
- Bone-healthy lifestyle:
  - Calcium and vitamin D based on age and gender requirements
- Drug therapy:
  - 1st line: 1a: bisphosphonate
    - 1b: denosumab
  - 2nd line: teriparatide or raloxifene
  - 3rd line: intranasal calcitonin

Bone healthy lifestyle:
- Calcium and vitamin D based on age and gender requirements
- Reevaluate BMD in 5 years or as appropriate.

Obtain baseline central BMD testing for monitoring response to therapy.

Reevaluate BMD in 1–2 years.

---

**a** Major risk factors: Current smoker, personal history of fracture as an adult (after age 50 years), history of low-trauma fracture in a first-degree relative, low BMD, low body weight/BMI, excessive alcohol use, chronic glucocorticoid use (3 months or longer).

**b** Secondary causes: Hypogonadism, rheumatoid arthritis, chronic obstructive pulmonary disease, systemic glucocorticoids.

**c** Bone-healthy lifestyle: Smoking cessation, well-balanced diet, weight-bearing/resistance exercise, fall prevention for seniors, and limiting alcohol. Calcium and vitamin D values based on IOM and NOF recommendations for age and gender.

**d** Alendronate, risendronate, and zoledronic acid are first line for men and women. Ibandronate is a second-line bisphosphonate and not FDA approved for use in men. IV bisphosphonates are generally an option if patient cannot tolerate oral bisphosphonates or has significant adherence problems.

**e** Denosumab may be used as a first-line agent per AACE 2010 guidelines.

**f** Teriparatide is FDA approved for use in men and can be considered a first-line option with a T-score less than –3.5 or if multiple low trauma fractures.

**g** Raloxifene may be a good option for women at high risk for breast cancer.

**h** Calcitonin is not FDA approved for use in men.

---

To increase with long-term bisphosphonate therapy of 7 to 10 years. Although increases in BMD have been reported at other sites, most of the clinically significant increases occur in the hip or spine and are an important marker of treatment effects. Bisphosphonate therapy can also prevent vertebral and non-vertebral fractures, decreasing the vertebral fracture risk by as much as 40% to 50% with oral bisphosphonates and up to 70% with zoledronic acid. IV zoledronic acid has also shown a 28% decrease in mortality associated with hip fracture. The most notable adverse effects associated with the oral bisphosphonates are GI, ranging from relatively mild nausea, vomiting, and diarrhea to more severe esophageal irritation and
esophagitis. Other common adverse reactions include dyspepsia, abdominal pain, nausea, and esophageal reflux. Esophageal ulceration, erosions with bleeding, perforation, stricture, and esophagitis may also occur. Upper GI adverse effects occur in up to 20% of patients and are often related to inappropriate administration. Advanced age, previous upper GI tract disease, and use of nonsteroidal anti-inflammatory drugs also increase the risk for GI adverse events, whereas once-weekly administration of oral bisphosphonates may decrease the risk.

Up to 40% of patients receiving the first dose of IV zoledronic acid may experience acute-phase reactions (flu-like symptoms) that can last for days, such as headache, arthralgia, myalgia, and fever.\(^1\) Pretreatment with acetaminophen may prevent these symptoms.\(^2\) Patients with moderate to severe renal impairment, severe dehydration, or taking concomitant diuretics or nephrotoxic drugs may be at higher risk of developing acute renal failure with zoledronic acid. Laboratory monitoring, including serum creatinine, alkaline phosphatase, phosphate, magnesium, and calcium, is recommended prior to administration of each zoledronic acid dose.

Long-term administration of bisphosphonates is considered beneficial in patients at high risk for fracture. However, for women who must discontinue bisphosphonate therapy due to intolerance or adverse events, improvements in BMD may be sustained.\(^15\) Although bisphosphonates have demonstrated continued efficacy over time, there are some safety concerns with long-term use. Serious adverse events including osteonecrosis of the jaw (ONJ),\(^16\)\(^19\) subtrochanteric fractures,\(^18\) and nonvertebral atraumatic fractures\(^19\) have been reported. These events may be related to oversuppression of bone turnover causing weakening of bone structure related to inhibition of osteoclastic activity.\(^20\)\(^21\) Risk factors for development of ONJ include chemotherapy, radiotherapy, corticosteroids, infection, or preexisting dental disease. Most cases of ONJ occurred in patients receiving high doses of zoledronic acid for cancer-related indications.\(^18\) Patients should complete major dental work prior to initiation of bisphosphonate therapy. The rate of subtrochanteric fractures also increases with more than 5 years of use.\(^22\) The NOF recommends reevaluation of therapy after 3 to 5 years of use and to stop treatment in patients who are at moderate risk of fractures.\(^1\) Esophageal cancer has also been reported with long-term therapy, but data are currently inconclusive.\(^24\)\(^25\)

Oral bisphosphonates are poorly absorbed (less than 5%). Taking them in the presence of food or calcium supplementation further reduces absorption. After absorption, bisphosphonate uptake to the primary site of action is rapid and sustained. Once attached to bone tissue, bisphosphonates are released very slowly over several years.

Proper drug administration is important for optimal absorption. Bisphosphonates should be taken 30 to 60 minutes prior to the first meal or food in the morning after an overnight fast with 6 to 8 oz of food. Proper drug administration is important for optimal absorption. Bisphosphonates should be taken 30 to 60 minutes prior to the first meal or food in the morning after an overnight fast with 6 to 8 oz of food.

| Alendronate (Fosamax)                     | 5-, 10-, 35-, 70-mg tablets; 70-mg with cholecalciferol 2800 IU; 70-mg with cholecalciferol 5600 IU; 70-mg oral solution | Prevention of PM osteoporosis: 5 mg orally daily or 35 mg orally once weekly  
Osteoporosis (men and women): 10 mg orally once daily or 70 mg orally once weekly  
Glucocorticoid-induced osteoporosis: 10 mg once daily  
Avoid when CrCl < 35 mL/min (0.58 mL/s) | Take after an overnight fast with 6–8 oz (180–240 mL) plain water while sitting or standing upright at least 30 minutes prior to morning meal.  
Do not lie down for 30 minutes after administration.  
Do not take with other medications or fluids.  
Do not chew or suck on the tablet.  
Same as alendronate except administer at least 1 hour prior to morning meal and refrain from lying down for 1 hour after administration. |
| Ibandronate (Boniva)                      | 2.5-, 150-mg tablets; 3-mg/3 mL injection | Treatment or prevention of PM osteoporosis: 2.5 mg orally daily or 150 mg orally once monthly; 3 mg IV push over 15–30 seconds every 3 months  
PM osteoporosis: 5 mg orally daily, 35 mg orally once weekly, 75 mg on 2 consecutive days each month, or 150 mg once monthly  
Male osteoporosis: 35 mg orally weekly or 150 mg orally monthly  
Glucocorticoid-induced osteoporosis: 5 mg orally daily  
Avoid when CrCl < 30 mL/min (0.50 mL/s) | Same as alendronate.                                                                                     |
| Risedronate (Actonel)                     | 5-, 35-, 75-, 150-mg tablets; 35-mg with 1250-mg calcium carbonate tablets | Prevention of PM osteoporosis: 5 mg infused IV over 15 minutes or longer every 24 months  
Treatment of osteoporosis (men and women), glucocorticoid-induced osteoporosis: 5 mg infused IV over 15 minutes or longer every 12 months  
Avoid when CrCl < 35 mL/min (0.58 mL/s) | Infuse over at least 15 minutes.  
May premedicate with acetaminophen.                                                                 |
| Zoledronic acid (Reclast)                 | 5 mg/100 mL IV infusion         | Prevention of PM osteoporosis: 5 mg infused IV over 15 minutes or longer every 24 months  
Treatment of osteoporosis (men and women), glucocorticoid-induced osteoporosis: 5 mg infused IV over 15 minutes or longer every 12 months  
Avoid when CrCl < 35 mL/min (0.58 mL/s) |                                                                                |

| Denosumab (Prolia)                        | 60 mg/mL SC prefilled syringe | PM or male osteoporosis: 60 mg SC every 6 months                                       | Inject in the upper arm, upper thigh, or abdomen.  
Keep refrigerated.                                                                   |
| **Recombinant Human Parathyroid Hormone** |                                |                                                                                      |                                                                                |
| Teriparatide (Forteo)                     | 250 mcg/mL, 2.4-mL prefilled pen | Osteoporosis (men and women), glucocorticoid-induced osteoporosis: 20 mcg SC daily | Inject into thigh or abdominal wall.  
Keep pen refrigerated.                                                                 |
| **Estrogen Agonists/Antagonists**         |                                |                                                                                      |                                                                                |
| Raloxifene (Evista)                       | 60-mg tablets                  | PM Osteoporosis: 60 mg daily                                                         | May be taken with or without food.  
Only for short duration.                                                               |
| Bazedoxifene/conjugated estrogens (Duavee)| 20 mg/0.45 mg                  | PM Osteoporosis + menopausal symptoms: one tablet daily                                |                                                                                |
| **Calcitonin**                            |                                |                                                                                      |                                                                                |
| Calcitonin salmon (Miacalcin)             | 200 IU/0.9 mL, 3.7-mL nasal spray | PM osteoporosis: Nasal spray: 200 IU daily                                              | Nasal spray: Alternate nostrils on a daily basis.                                 |

CrCl, creatinine clearance; PM, postmenopausal; SC, subcutaneously.

(about 180–240 mL) of water (or 2 oz [60 mL] with the oral solution). Administration should be with water only and not combined with other fluids. Patients should remain upright and refrain from lying down for 30 to 60 minutes after administration. The tablets should be swallowed whole without chewing or sucking. Bisphosphonates should not be taken with other medications or dietary supplements. Bisphosphonates are not recommended for use in patients with esophageal abnormalities that may delay transit of the tablet, such as with severe GERD, achalasia, stricture, or Barrett esophagus. They are also not recommended in patients with hypocalcemia or renal insufficiency or failure (creatinine clearance less than 30 to 35 mL/min [0.50–0.58 mL/s]), or in those who are pregnant. For patients who are unable to tolerate or have a contraindication to oral bisphosphonates, IV agents may be used.

**Denosumab**

Denosumab is the first human monoclonal antibody FDA approved for treatment of postmenopausal osteoporosis. It is first-line therapy and should be considered in patients who are unable to tolerate bisphosphonates due to GI contraindications...
or side effects and for patients with malabsorption or adherence issues. Denosumab reduces nuclear factor-kappa B ligand (RANKL) action, which leads to selective inhibition of osteoclast formation, function, and survival. In contrast to bisphosphonates, the antiresorptive effects of denosumab are reversible.

Denosumab has been shown to increase BMD in the hip and spine by up to 6% and 9%, respectively; and decrease hip, vertebral, and nonvertebral fracture risk by up to 40%, 68%, and 20%, respectively. Patients treated with denosumab had greater increases in hip and spine BMD than patients treated with alendronate, although fracture rate was not reported. In a long term, open-label study use of denosumab for 6 years resulted in continued increases in BMD up to 15% in the lumbar spine and up to 7% at the hip; a reduction in fracture rates was sustained compared to denosumab use for 3 years.

Common adverse effects include back pain, arthralgias, fatigue, headache, dermatologic reactions, diarrhea, and nausea. Serious adverse reactions, including hypophosphatemia, hypocalcemia, dyspnea, and skin and other infections, can also occur. Patients should seek medical attention if they experience any symptoms of infection. Denosumab can worsen hypocalcemia in predisposed patients, such as those with severe kidney disease, and preexisting hypocalcemia should be corrected before initiating therapy. Suppression of bone turnover has been associated with denosumab therapy, and ONJ has also been reported.

Denosumab is part of a Risk Evaluation and Mitigation Strategy (REMS) program, in which the manufacturer is required by the FDA to inform patients and health care providers of the risks associated with its use. Denosumab is administered as a subcutaneous injection once every 6 months and should be stored in the refrigerator until administration. Once at room temperature, the vial or prefilled syringe must be used within 14 days. Prescribing information recommends administration of 1000 mg of calcium and at least 400 IU of vitamin D once daily.

**Teriparatide**

Teriparatide, recombinant human parathyroid hormone (1–34), is the first anabolic agent approved by the FDA for treatment of postmenopausal and male osteoporosis. It is generally reserved for patients with very high fracture risk or those in whom other therapies have been ineffective. This agent differs from antiresorptive therapies in that it stimulates osteoblastic activity to form new bone. It is administered as a daily subcutaneous injection. Teriparatide increases BMD in the spine and hip by 9% and 3%, respectively; and reduces fracture rate by 65% and 53% in vertebral and nonvertebral fractures, respectively. Significant reductions in hip fracture have not been demonstrated.

Common adverse effects include nausea, headache, leg cramps, dizziness, injection site discomfort, and hypercalcemia. Orthostatic hypotension may also occur; patients should be seated after the first several doses until drug response is predictable. Teriparatide should not be used in patients with preexisting hypercalcemia. Observations of osteosarcoma in animal studies led to the inclusion of a “black box warning” in the product labeling, but no cases have been reported in humans. Patient-related concerns regarding the use of teriparatide include cost of therapy and need for daily subcutaneous injections. The labeling recommends treatment for a maximum of 2 years because it has not been studied for longer periods.

**Selective Estrogen Receptor Modulators (SERMs)**

Raloxifene is an SERM indicated for prevention and treatment of osteoporosis. It is recommended as alternative therapy after bisphosphonates, denosumab, or teriparatide. It has estrogen-like activity on bones and cholesterol metabolism and estrogen antagonist activity in breast and endometrium. It reduces bone resorption and decreases overall bone turnover.

Raloxifene has been shown to increase BMD in the vertebra (2%–3%) and hip (1%–2%), and reduce vertebral fracture rates by as much as 55%. Significant decreases in nonvertebral fractures have not been demonstrated. Raloxifene has been shown to decrease the incidence of breast cancer in high-risk women. It also decreases total and low-density lipoprotein (LDL) cholesterol, which generated initial enthusiasm for additional cardiovascular benefits. However, mixed results have been seen on cardiovascular disease, stroke, and noncardiovascular mortality.

Adverse effects of raloxifene include hot flushes, leg cramps, and increased risk of venous thromboembolism. A previous history of venous thromboembolism is a contraindication to therapy. Hot flushes are very common and may be intolerable in postmenopausal women who are already predisposed to experiencing them. Raloxifene is pregnancy category X and is contraindicated in women who are pregnant or may become pregnant, and in nursing mothers.

Bazedoxifene, a third-generation estrogen agonist/antagonist, has similar effects to raloxifene. At the time of this writing, it was marketed only for short-term use as a combination product with conjugated estrogens (Duavee) for treatment of moderate to severe vasomotor symptoms associated with menopause and for prevention of postmenopausal osteoporosis. A single-ingredient product, bazedoxifene acetate (Viviant), was investigational at the time of this writing.

**Calcitonin**

Calcitonin is a naturally occurring mammalian hormone that plays a major role in regulating calcium levels. It inhibits bone resorption by binding to osteoclast receptors. Calcitonin is considered a last-line agent for the treatment of osteoporosis. Calcitonin produces a modest increase in BMD at the spine of 1% to 3% and reduces vertebral fracture risk by up to 30%. However, no benefit has been demonstrated in reducing nonvertebral fractures. Calcitonin was previously thought to provide analgesic effects in women with back pain from vertebral fractures, but recent practice trends favor managing fracture risk and pain separately.

Although salmon calcitonin is approved and available in injectable and intranasal formulations, only the intranasal formulation has documented benefit in clinical trials for management of osteoporosis. Adverse effects associated with the intranasal formulation include rhinitis, nasal irritation, and dryness. Hypersensitivity can develop with either formulation and should be considered before administering to patients with suspected risk.

**Hormone Therapy**

Estrogen, either alone or in combination with a progestin as hormone replacement therapy (HRT), has a long history as an effective treatment of osteoporosis. The Women’s Health Initiative (WHI) trial found a 34% reduction in both vertebral and hip fractures and a 23% reduction in other fractures in postmenopausal women receiving conjugated estrogens and medroxyprogesterone. However, significant risks associated with long-term HRT, including breast cancer and venous thromboembolism, have limited its use in osteoporosis.
**Combination and Sequential Therapy**
Interest in combination therapy with two or more osteoporosis drugs is based on the idea that using agents with differing mechanisms would result in greater increases in BMD and reductions in fracture rates. Combination therapies with two antiresorptive agents or an anabolic agent coupled with an antiresorptive agent have shown modest benefit on BMD and markers of bone turnover. Data on fracture reduction are lacking. Interest in sequential therapy (anabolic agent followed by antiresorptive therapy) stems from the limited duration (2 years) of teriparatide use and the rapid decline in beneficial effects on bone once teriparatide is discontinued. Due to high cost and lack of long-term safety and efficacy data, the AACE does not recommend combination antiresorptive therapy for treating osteoporosis. The NOF prefers sequential therapy over combination therapy but acknowledges that combination antiresorptive and anabolic therapies could be considered for patients with very severe osteoporosis.

**Investigational Agents**
Several anabolic and antiresorptive therapies are under investigation for treatment of osteoporosis. The most promising antiresorptive therapy may be odanacatib, a selective enzyme inhibitor of cathepsin-K, which prevents enzymatic bone degradation in mature osteoclasts. Anabolic therapies currently under investigation include calcilytic drugs and Wnt pathway modulators. Calcilytic drugs increase bone formation by imitating hypocalcemia and cause parathyroid hormone secretion. Wnt signaling pathway modulators promote osteoblastic bone formation. Romosozumab, a monoclonal antisclerostin antibody, binds to sclerostin, a Wnt antagonist, to increase bone formation. These agents are currently in phase 1 and 2 trials. Other investigational therapies, strontium ranelate, PTH (1–84), and tibolone, are available outside the United States.

**Treatment of Special Populations**

> **Glucocorticoid-Induced Osteoporosis**
Glucocorticoids play a significant role in bone remodeling. Exogenous glucocorticoid administration increases bone resorption, inhibits bone formation, and changes bone quality. Glucocorticoids (eg, prednisone, hydrocortisone, methylprednisolone, and dexamethasone) promote bone resorption through reduced turnover. Data on fracture reduction are lacking. Consideration of alternate therapies if the initial therapy fails or is intolerable.

---

**Patient Encounter, Part 3: Development of a Treatment Plan**
Considering all of the information presented, develop a treatment plan for this patient. Include the following information:

- **Recommendations for patient-specific drug therapy including dose and frequency.**
- **Patient education about the chosen regimen, including administration directions.**
- **Monitoring plan for efficacy and adverse effects.**
- **Consideration of alternate therapies if the initial therapy fails or is intolerable.**

---

**Patient Care Process**

**Patient Assessment:**
- Assess risk factors for osteoporosis and presence of secondary causes of osteoporosis.
- Assess nonpharmacologic interventions for preventing osteoporotic fractures, including nutrition and weight-bearing and muscle-strengthening exercise regimens. What is the patient’s fall risk?
- Determine average calcium intake from diet (see Table 56–4) and supplements (see Table 56–5) and evaluate the patient’s sources of vitamin D. Based on age, gender and laboratory values, is the patient receiving appropriate calcium and vitamin D supplementation?
- Test bone densitometry in patients at risk for having low bone mass or bone loss. If T-score is between –1.0 and –2.5, use FRAX to estimate fracture risk.

**Therapy Evaluation:**
- Perform a thorough medication history, including prescription, over-the-counter, and alternative therapies. Does the patient take any calcium and vitamin D supplements?
- If drug therapy is indicated, assess the patient for contraindications.
- If the patient is already receiving pharmacotherapy, assess efficacy, safety, and patient adherence. How long has the patient been on each agent? Was the patient previously trialed with other agents?
- Determine what options are available for the patient. Does the patient have prescription coverage? What agents are recommended on the formulary?

**Care Plan Development:**
- Select therapy (including agent and dose) likely to be safe and effective for the patient (see Table 56–6).
- Educate the patient on drug therapy selected, including drug name, dose, route and method of administration, common or serious adverse reactions, adherence, and monitoring.
- Educate the patient about nonpharmacologic measures to prevent osteoporotic fractures.
- Discuss therapeutic goals and expectations (eg, changes in individual T-scores may not necessarily correlate with benefit in fracture risk reduction).

**Follow-Up Evaluation:**
- Annually review the need for continued medication. Assess appropriate drug administration, efficacy, adverse effects, and nonpharmacologic measures to prevent fractures.
calcium absorption from the GI tract and increased renal calcium excretion. Bone formation is reduced through inhibition of osteoblasts and decreased estrogen and testosterone production.

Patients receiving long-term glucocorticoids are at increased risk of fracture, which is greater with higher doses and longer-term therapy. Most bone mass is lost during the initial 6 to 12 months of therapy but it continues to decline thereafter. Due to the risk of bone loss and fractures, therapy is recommended for patients receiving long-term supraphysiological doses of glucocorticoids.

In addition to nonpharmacologic measures, the American College of Rheumatology (ACR) has specific recommendations for preventing and treating patients receiving glucocorticoids. Recommendations for optimal calcium and vitamin D intake are higher and include 1200 to 1500 mg daily of elemental calcium and 800 to 1000 IU daily of vitamin D, or higher as needed to maintain adequate 25(OH)D levels, for all adults receiving glucocorticoids.

**KEY CONCEPT** The ACR recommends bisphosphonate therapy with alendronate or risedronate for all patients who are starting treatment with glucocorticoids (prednisone 5 mg or more daily or equivalent) that will continue for 3 months or longer. Therapy may also be started in patients with lower glucocorticoid doses or shorter duration based on risk factors for fracture. Zoledronic acid and teriparatide may also be considered for moderate- to high-risk patients. Although not FDA approved, denosumab has been studied in this population and may be considered an alternate therapy for patients nonresponsive to or intolerant of other therapies.

**OUTCOME EVALUATION**

- Evaluate patients for progression of osteoporosis, including signs and symptoms of new fragility fracture (eg, localized pain), loss of height, and physical deformity (eg, kyphosis). Assess patients on an annual basis or more often if new symptoms present
- Monitor for beneficial effects on bone density. The NOF recommends a follow-up DXA scan every 2 years to monitor the effects of therapy
- Assess patients for adverse effects of therapy:
  - Oral bisphosphonates: Dyspepsia, esophageal reflux, esophageal pain, or burning
  - Injectable zoledronic acid: Influenza-type symptoms related to infusion, ONJ (rare)
  - Denosumab: Arthralgias, dermatologic reactions, and hypocalcemia
  - Teriparatide: Nausea, headache, leg cramps, hypercalcemia
  - Raloxifene: Hot flushes, signs, or symptoms of thromboembolic disease (eg, pain, redness, or swelling in one extremity, chest pain, and shortness of breath)
  - Calcitonin salmon: Nasal irritation or burning

**Abbreviations Introduced in This Chapter**

ACR  American College of Rheumatology
BMD  Bone mineral density
BMI  Body mass index
DXA  Dual-energy x-ray absorptiometry
HRT  Hormone replacement therapy
NOF  National Osteoporosis Foundation

**REFERENCES**

INTRODUCTION

Rheumatoid arthritis (RA) is a complex systemic inflammatory condition manifesting initially as symmetric swollen and tender joints of the hands and/or feet. Some patients may experience mild articular disease, whereas others may present with aggressive disease and/or extraarticular manifestations. The systemic inflammation of RA leads to joint destruction, disability, and premature death. Juvenile idiopathic arthritis (JIA) is the most common form of arthritis in children.

Epidemiology and Etiology

RA has a prevalence of 0.5% to 1%. Patients with RA have a 50% increased risk of premature death and a decreased life expectancy of 3 to 10 years compared with individuals without RA. The underlying causes of increased mortality are unclear. RA arises from an immunologic reaction, perhaps in response to a genetic or infectious antigen. Risk factors associated with the development of RA include the following:

- Female gender (3:1 females to males)
- Increasing age (peak onset 35–50 years of age)
- Current tobacco smoking. Tobacco users are more likely to have extraarticular manifestations and to experience treatment nonresponsiveness. This risk is reduced when a patient has remained tobacco-free for at least 10 years.
- Family history of RA. Genetic studies demonstrate a strong correlation between RA and the presence of major histocompatibility complex class II human leukocyte antigens (HLA), specifically HLA-DR1 and HLA-DR4.

HLA is a molecule associated with the presentation of antigens to T lymphocytes.

- Emerging evidence suggests that stress may influence RA onset and disease activity. It appears that individual major stressful life events do not play a significant role. Instead, chronic presence of minor stressors (daily hassles, work and relationship stress, financial pressures) may affect the immune response and RA disease activity.
- The prevalence of JIA is approximately 1 in 1000 children. There are no known risk factors for JIA.

Pathophysiology

The characteristics of a synovium affected by RA are: (a) the presence of a thickened, inflamed membrane lining called pannus; (b) development of new blood vessels; and (c) influx of inflammatory cells in the synovial fluid, predominantly T lymphocytes. The pathogenesis of RA is driven by T lymphocytes, but the initial catalyst causing this response is unknown. Understanding specific components of the immune system and their involvement in the pathogenesis of RA will facilitate understanding of current and emerging treatment options for RA. The components of most significance are T lymphocytes, cytokines, B lymphocytes, and kinases.

T Lymphocytes

The development and activation of T lymphocytes are important to maintain protection from infection without causing harm to the host. Activation of mature T lymphocytes requires two signals. The first is the presentation of an antigen by
antigen-presenting cells to the T-lymphocyte receptor. Second, a ligand-receptor complex (ie, CD80/CD86) on antigen-presenting cells binds to CD28 receptors on T lymphocytes. Once a cell successfully passes through both stages, the inflammatory cascade is activated. Activation of T lymphocytes: (a) stimulates the release of macrophages or monocytes, which subsequently causes the release of inflammatory cytokines; (b) activates osteoclasts; (c) activates release of matrix metalloproteinases or enzymes responsible for the degradation of connective tissue; and (d) stimulates B lymphocytes and the production of antibodies.

Cytokines

Cytokines are proteins secreted by cells that serve as intercellular mediators (Table 57–1). An imbalance of proinflammatory and anti-inflammatory cytokines in the synovium leads to inflammation and joint destruction. Some of the proinflammatory cytokines are interleukin 1 (IL-1), tumor necrosis factor-α (TNF-α), IL-6, and IL-17. These proinflammatory cytokines cause activation of other cytokines and adhesion molecules responsible for recruitment of lymphocytes to the site of inflammation. Anti-inflammatory cytokines and mediators (IL-4, IL-10, and IL-1 receptor antagonist) are present in the synovium, although concentrations are not high enough to overcome the effects of the proinflammatory cytokines.

B Lymphocytes

In addition to serving as antigen-presenting cells to T lymphocytes, B lymphocytes may produce proinflammatory cytokines and antibodies. Antibodies of significance in RA are rheumatoid factors (antibodies reactive with the Fc region of IgG) and anticitrullinated protein antibodies (ACPA). Rheumatoid factors are not present in all patients with RA, but their presence is indicative of disease severity, likelihood of extraarticular manifestations, and increased mortality. ACPA are produced early in the course of disease. High levels of ACPA are indicative of aggressive disease and a greater likelihood of poor outcomes. Monitoring ACPA may be useful to predict the severity of disease and match aggressive treatment appropriately.

### Key Concept

The comorbidities with the greatest impact on morbidity and mortality associated with RA are: (a) cardiovascular disease, (b) infections, (c) malignancy, and (d) osteoporosis.

### Cardiovascular Disease

More than half of all deaths in RA patients are cardiovascular related. Because a patient with RA experiences inflammation and swelling in joints, it is likely that there is inflammation elsewhere, such as in the blood vessels, termed vasculitis. C-reactive protein (CRP), a nonspecific marker of inflammation, is associated with an increased risk of cardiovascular disease; CRP is elevated in patients with RA. Traditional cardiovascular risk factors alone cannot explain the increased cardiovascular mortality in patients with RA. Increasing evidence suggests that the presence of RA is a cardiovascular risk similar to diabetes. Aggressive management of systemic inflammation and traditional cardiovascular risk factors (eg, blood pressure, cholesterol, tobacco use) may reduce cardiovascular mortality in this population.

### Infections

RA itself leads to changes in cellular immunity and causes a disproportionate increase in infections. Because medications that alter the immune system increase infection risk, it is difficult to distinguish between an increased risk due to RA and the immunosuppressive therapy. Patients and clinicians must pay close attention to signs and symptoms of infection.

► Malignancy

Cancer is the second most common cause of death in RA patients. There is increased risk of developing lymphoproliferative malignancy (eg, lymphoma, leukemia, multiple myeloma), skin, and lung cancer but decreased risk of developing cancer of the breast and digestive tract. The relationship between RA and cancer is not clear. To confound the issue, medications for treating RA are undergoing review to determine whether use independently increases cancer risk. Current evidence suggests that the use of biologic medications does not increase the baseline risk associated with disease alone.

► Osteoporosis

Osteoporosis associated with RA follows a multifaceted pathogenesis, but the primary mechanism likely is mediated by increased osteoclast activity. The cytokines involved in the inflammatory process directly stimulate osteoclast and inhibit osteoblast activity. Additionally, arthritis medications can lead to increased bone loss. Bone mineral density should be evaluated at baseline and routinely using dual-energy x-ray absorptiometry.

CLINICAL PRESENTATION AND DIAGNOSIS

See the box on next page for the clinical presentation of RA.

Diagnosis

Both osteoarthritis and RA are prevalent in the U.S. population, but they differ in presentation (Table 57–2). Because management of the two conditions differs significantly, early evaluation and diagnosis are essential to maximize an individual patient’s care.

In 2010, The American College of Rheumatology (ACR) and European League Against Rheumatism (EULAR) released new classification criteria for RA (Table 57–3). The goal was to identify a subset of patients with undifferentiated synovitis who were at high risk for chronic and erosive disease. The criteria are intended to help identify patients earlier in the course of disease. This will allow researchers to determine whether earlier introduction of medications alters the disease process. The criteria were developed as a tool for research purposes, but they are also helpful to guide clinical diagnosis. Patients with at least one joint with definite clinical synovitis that is not explained by another disease should be tested for RA.

Several clinical features of RA are associated with a worse long-term prognosis. The presence of these poor prognostic features should be considered at the time initial treatment decisions are made; more aggressive treatment may be warranted if these features are present. The most clinically important features associated with poor long-term outcomes include: (a) functional limitation (defined by use of standard measurement scales such as the Health Assessment Questionnaire [HAQ] score),

TOTAL: 6 or greater indicates definite RA

ACPA, anticitrullinated protein antibodies; ACR, American College of Rheumatology; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; EULAR, European League Against Rheumatism; MCPs, metacarpophalangeal joints; MTPs, metatarsophalangeal joints; PIPs, proximal interphalangeal joints; RA, rheumatoid arthritis; RF, rheumatoid factor.
Clinical Presentation of RA

General
- About 60% of patients develop symptoms gradually over several weeks to months.
- Patients may present with systemic findings, joint findings, or both.

Symptoms
- Nonspecific systemic symptoms may include fatigue, weakness, anorexia, and diffuse musculoskeletal pain.
- Patients complain of pain in involved joints and prolonged morning joint stiffness.

Signs
- The metacarpophalangeal (MCP), proximal interphalangeal (PIP), metatarsophalangeal (MTP), and wrist joints are involved frequently.
- Joint involvement is usually symmetric.
- There is often limited joint function.
- Signs of joint inflammation are present (tenderness, warmth, swelling, and erythema).
- Low-grade fever may be present.
- Extraarticular manifestations:
  - Skin: Subcutaneous nodules
  - Ocular: Keratoconjunctivitis sicca, scleritis

Laboratory Tests
- Positive rheumatoid factor (the test is negative in up to 30% of patients)
- Elevated ESR (Westergren ESR: greater than 20 mm/hour in men; greater than 30 mm/hour in women)
- Elevated C-reactive protein (CRP) (greater than 0.7 mg/dL or 7 mg/L)
- Complete blood count: Slight elevation in WBC count with a normal differential; slight anemia; thrombocytosis
- Positive anticitrullinated protein antibodies (ACPA)

Other Diagnostic Tests
- Synovial fluid analysis: Straw colored, slightly cloudy, WBC 5–25 × 10^3/mm^3 (5–25 × 10^9/L), no bacterial growth if cultured
- Joint x-rays: To establish baseline and evaluate joint damage
- MRI: May detect erosions earlier in the course of disease than x-rays but is not required for diagnosis

(b) extraarticular disease, (c) positive rheumatoid factor, (d) positive ACPA, and/or (e) bony erosions by radiography.

Diagnosis of Juvenile Idiopathic Arthritis
Diagnostic criteria for JIA include: (a) age less than 16 years at disease onset, (b) arthritis in one or more joints for more than 6 weeks, (c) exclusion of other types of arthritis. JIA can be divided into three main types:

1. Systemic (4%–17% of cases): Occurs equally in girls and boys. There are characteristic fever spikes twice daily (greater than 38.3°C or 101°F) and the presence of a pale, pink, transient rash. The peak onset is between ages 1 and 6 years.

2. Polyarticular (approximately 40% of cases): More likely to affect girls than boys (3:1). Arthritis is present in five or more joints. The disorder resembles adult RA more than the other types of JIA.

3. Oligoarticular (about 50% of cases): More likely to affect girls than boys (5:1). Uveitis is more likely to be present. Arthritis is present in four or fewer joints. The peak onset is between ages 1 and 3 years.

TREATMENT
Desired Outcomes
- The goals of treatment in RA are to: (a) reduce or eliminate pain, (b) protect articular structures, (c) control systemic complications, (d) prevent loss of joint function, and (e) improve or maintain quality of life. The goals for JIA are the same, with the added goals of maintaining normal growth, development, and activity level. It is a common misconception that patients with JIA grow out of the disease. Many children with JIA become adults with JIA. Knowing this, it is essential that early, aggressive treatment is initiated to achieve the goals of therapy.

General Approach to Treatment
The clinician must evaluate patient-specific factors and select appropriate treatment to maximize the care of each patient.

Patient Encounter, Part 1
A 68-year-old woman presents to her rheumatologist with complaints of increased joint swelling in her hands and feet over the last 3 months. She is especially disturbed by daily morning joint stiffness that lasts for 90 minutes on average. She is retired but has a small business as a seamstress. She is falling behind on her business projects because of the daily limitations with her hands. She wishes to improve function in her hands as soon as possible before customers start complaining.

What information is suggestive of RA?
What risk factors does she have for RA?
What additional information do you need before creating a treatment plan for this patient?
What other variables in this scenario may inhibit optimal patient care?
Joint damage accumulates over time; therefore, early diagnosis and early aggressive treatment are necessary to reduce disease progression and prevent joint damage. Aggressive treatment is defined as one or more disease-modifying antirheumatic drugs (DMARDs) at effective doses. Delaying treatment will result in more destructive disease that is very difficult to delay or reverse to preserve joint function.

**KEY CONCEPT** It is imperative that the initiation of one or more DMARDs occurs in all patients within the first 3 months of diagnosis to reduce joint erosion. Depending on disease severity and whether poor prognostic features are present, combination therapy may be initiated at the time of diagnosis or after an adequate trial of a DMARD initiated as monotherapy. If a patient has more aggressive disease, a more aggressive treatment plan may be warranted. The following medication classes are prescribed commonly for treatment of RA: (a) nonsteroidal anti-inflammatory drugs (NSAIDs), (b) glucocorticoids, (c) conventional synthetic DMARDs (csDMARDs), (d) biological originator DMARDs (boDMARDs), and (e) targeted synthetic DMARDs (tsDMARDs).

An emerging drug category is biosimilar DMARDs (bsDMARDs). This category will include biological DMARDs that are a copy of the original biologic compound and demonstrate similar efficacy and safety. boDMARDs are currently in development and not yet available for general use. The nomenclature for DMARDs was proposed by an international leader in rheumatology to distinguish the different types of DMARDs.

**Figures 57–1 and 57–2 outline the course of treatment for adult RA according to the ACR 2012 Recommendations.**

![Image of a diagram outlining the treatment course for adult RA](image)

The recommendations are based on the disease activity level, presence or absence of poor prognostic features, and duration of disease activity (early vs established). Figure 57–1 applies to patients who have had RA for less than 6 months. csDMARD monotherapy includes hydroxychloroquine, leflunomide, methotrexate, minocycline, or sulfasalazine. Examples of combination therapy for patients with moderate or high disease activity with evidence of poor prognostic features are methotrexate/hydroxychloroquine, methotrexate/sulfasalazine, or methotrexate/sulfasalazine/hydroxychloroquine.

Figure 57–2 outlines the course of treatment for patients with established RA (disease duration 6 months or longer). boDMARDs are usually considered in patients with established RA following inadequate response to csDMARDs. Figure 57–2 establishes a progression for switching from one agent to another in a patient who experiences an inadequate response or adverse event. Because of treatment expense, boDMARDs should be considered only in patients who have no limitations due to cost or insurance coverage. There is no evidence that the benefits of combination boDMARD therapy outweigh the potential risks, especially the increased risk of infections.

**Nonpharmacologic Therapy**

All patients should receive education about the nonpharmacologic and pharmacologic measures to help manage RA and JIA. Empowered patients take an active role in care by participating in therapy-related decisions. Certain forms of nonpharmacologic therapy benefit all levels of severity, whereas others (ie, surgery) are reserved for severe cases only.
Occupational and physical therapy may help patients preserve joint function, extend joint range of motion, and strengthen joints and muscles through strengthening exercises. Patients with joint deformities may benefit from the use of mobility or assistive devices that help to minimize disablement and allow continued activities of daily living. When appropriate, patients should also be counseled about stress management (ie, cognitive behavioral therapy, emotional disclosure, tai chi). In situations where the disease has progressed to a severe form with extensive joint erosions, surgery to replace or reconstruct the joint may be necessary.

**Pharmacologic Therapy**

**Bridge Therapy/Symptomatic Relief**

The current standard of care for RA treatment is to initiate disease-modifying therapy immediately. While this step is critical to control the underlying disease activity, it may take weeks to months for the patient to experience relief. It is acceptable to initiate “bridge therapy” or short-term use of certain medications to provide symptomatic relief until the disease modifying drug reaches its therapeutic effect. The most common classes used for bridge therapy are NSAIDs and glucocorticoids.

**NSAIDs** These agents provide analgesic and anti-inflammatory benefits for joint pain and swelling. However, they do not prevent joint damage or change the underlying disease. Selecting an NSAID depends on multiple patient-specific factors, including cardiovascular risk, potential for GI-related adverse events, adherence to medication regimens, and insurance coverage or lack thereof. NSAID monotherapy is recommended as initial treatment in children with JIA without prior treatment for a duration of 1 month. Clinicians must carefully evaluate the potential risks of NSAID therapy against the potential benefits. See Chapter 58 for additional discussion of NSAID therapy.

**Glucocorticoids** In contrast to NSAIDs, low-dose glucocorticoid treatment (equivalent to prednisone 10 mg/day or less) effectively reduces inflammation through inhibition of cytokines and inflammatory mediators and prevents disease progression. However, due to the adverse effect profile, the goal of glucocorticoid use is to keep doses low and use the drugs as infrequently as possible. Patients taking more than 5 mg/day of prednisone or equivalent are at increased risk for clinically significant adverse reactions, especially bone loss leading to osteoporosis. Other glucocorticoid-related adverse reactions include Cushing syndrome, peptic ulcer disease, hypertension, weight gain, infection, mood changes, cataracts, dyslipidemia, and hyperglycemia. A modified-release dosage form of prednisone is available and is intended to improve the benefit-to-risk ratio of glucocorticoid use. Intraarticular glucocorticoid injections are recommended as initial treatment of JIA for disease affecting four or fewer joints.

**Conventional Synthetic DMARDs (csDMARDs)**

DMARDs are the mainstay of RA treatment because they modify the disease process and prevent or reduce joint damage. In addition to relying on safety and efficacy data, the initial DMARD choice depends on disease severity, patient characteristics (ie, comorbidities, likelihood of adherence), cost, and clinician experience with the medication. Methotrexate alone or in combination therapy is the initial treatment of choice for patients with aggressive disease. Agents such as azathioprine, D-penicillamine, gold salts, and anakinra are used rarely today because of concerns about toxicity and reduced efficacy.

**Methotrexate** Methotrexate is the csDMARD of choice in RA because of its documented efficacy and safety profile when monitored appropriately. Methotrexate exerts its anti-inflammatory effect through inhibition of dihydrofolate reductase, which causes inhibition of purines and thymidylic acid, and by inhibiting production of certain cytokines. Unless the patient has contraindications to methotrexate, once-weekly doses should be initiated within 3 months of diagnosis and increased steadily until the patient has symptomatic improvement or a maximum dose of 20 mg/wk is reached. If monotherapy does not produce complete resolution of symptoms, methotrexate may be used in combination with other csDMARDs or boDMARDs. Concomitant folic acid is given routinely to reduce the risk of folate-depleting reactions induced by methotrexate therapy (eg, stomatitis, diarrhea, nausea, alopecia, myelosuppression, and elevations in liver function tests).

Methotrexate is recommended as initial treatment for JIA in patients with more than four active joints. There are insufficient published data to assess the risk of serious toxicity in children receiving doses greater than 20 mg/m²/week. Methotrexate therapy in children should be monitored the same way that is recommended in adults.

**Hydroxychloroquine and Sulfasalazine** The exact mechanism of action of these drugs is unknown, but both agents are fairly well tolerated. Hydroxychloroquine or sulfasalazine may be initiated on diagnosis of low disease activity. Because of their slow onset of action, each drug must be given at therapeutic doses for at least 6 months before it can be deemed a treatment failure. Hydroxychloroquine and sulfasalazine are relatively inexpensive compared to boDMARDs. If a patient does not respond to methotrexate monotherapy, adding one of these two drugs may provide the benefit necessary to reduce symptoms satisfactorily and ideally induce remission.

Hydroxychloroquine is not associated with renal, hepatic, or bone marrow suppression and therefore may be an acceptable treatment option for patients with contraindications to other DMARDs because of their toxicities.

Starting sulfasalazine at low doses and titrating slowly will minimize the nausea and abdominal discomfort caused by the drug. Patients receiving sulfasalazine must undergo routine blood work to monitor for leukopenia. Patients with a sulfa allergy should not receive sulfasalazine.

In patients with JIA, sulfasalazine is recommended only for patients with the enthesis-related category. Enthesitis-related arthritis is a less common form of JIA that affects boys more than girls and is characterized by lower extremity joint involvement, including heel pain and enthesis. Hydroxychloroquine is not recommended in JIA patients with active arthritis.

**Leflunomide** This drug inhibits dihydroorotate dehydrogenase, an enzyme within mitochondria that supplies T lymphocytes with the necessary components to respond to cytokine stimulation. Thus, leflunomide inhibits the T-lymphocyte response to various stimuli and halts the cell cycle. Its efficacy is similar to that of moderate doses of methotrexate or sulfasalazine. Because of its extended half-life, leflunomide therapy begins with a loading dose followed by a maintenance dose. Leflunomide may be used in combination with methotrexate, but the added efficacy comes with a dramatic rise in the risk of hepatotoxicity. If therapy requires abrupt discontinuation (eg, due to toxicity or pregnancy), administering cholestyramine will accelerate leflunomide removal from the body.

Leflunomide is recommended as an alternative to methotrexate in patients with JIA experiencing disease activity in five or more joints. However, leflunomide does not have an FDA-approved indication for this use.
**Biological Originator DMARDs (boDMARDs)**

boDMARDs are indicated in patients who have failed an adequate trial of csDMARD therapy or in combination with csDMARDs in patients with early, aggressive disease. These agents may be added to csDMARD monotherapy (eg, methotrexate) or replace ineffective csDMARD therapy. The decision to select a particular agent generally is based on the prescriber’s comfort level with monitoring the safety and efficacy of the medications, severity of disease activity, presence of factors suggestive of poor prognosis, the frequency and route of administration, the patient’s comfort level or manual dexterity to self-administer subcutaneous injections, the cost, and the availability of insurance coverage. In general, boDMARDs should be avoided in patients with serious infections, demyelinating disorders (eg, multiple sclerosis), or hepatitis. TNF antagonists should be avoided in patients with heart failure.

**Tumor Necrosis Factor Antagonists**

Etanercept is a recombinant form of human TNF,21 Etanercept provides a therapeutic effect by binding to soluble TNF and preventing its binding with TNF receptors. Etanercept is very effective as monotherapy or in combination with other csDMARDs. Etanercept has an FDA-approved indication for treatment of JIA.

Adalimumab is a recombinant human IgG1 monoclonal antibody specific for human TNF.22 Adalimumab binds to soluble and bound TNF-α. It can be administered in combination with methotrexate or other DMARDs.22 Adalimumab has an FDA-approved indication for JIA.

Infliximab is a chimeric IgG1 monoclonal antibody that binds to soluble and bound TNF-α.23 Methotrexate typically is given with it to suppress antibody production against the mouse-derived portion of the molecule. Qualified healthcare personnel must be present during the infliximab infusion to respond to infusion-related reactions, if they occur (rash, urticaria, flushing, headache, fever, chills, nausea, tachycardia, dyspnea). These reactions may be treated by: (a) temporarily discontinuing the infusion, (b) slowing the infusion rate, or (c) administering corticosteroids or antihistamines. Patients may be pretreated with corticosteroids or antihistamines if they continue to experience infusion reactions. Infliximab was shown in clinical trials to be effective for treatment of JIA, but it has not yet received FDA approval for this indication.

Golimumab is a human monoclonal antibody that binds to membrane-bound and soluble TNF.22 Golimumab can be administered in combination with methotrexate in patients with moderate to severe RA. One advantage of this agent over others in the class may be the once-monthly SC dosing or every-other-month IV dosing. Golimumab is not FDA approved for use in JIA.

Certolizumab is a humanized antibody Fab fragment conjugated to polyethylene glycol, which delays its metabolism and elimination.22 Certolizumab can be administered alone or in combination with methotrexate in patients with moderate to severe RA. Certolizumab is not FDA approved for use in JIA.

**Interleukin-1 Receptor Antagonist**

Anakinra is a recombinant form of human IL-1 receptor antagonist.21 Anakinra inhibits the activity of IL-1 by binding to it and preventing cell signaling. It is indicated for adults with RA who have failed one or more csDMARDs. It may be used in combination with other csDMARDs in patients not responding to or unable to tolerate csDMARDs or TNF antagonists. Anakinra is not included in the 2012 treatment algorithms due to limited efficacy and infrequent use in RA. Regarding treatment of JIA, anakinra is recommended in the ACR treatment guidelines for patients with systemic arthritis with continued disease activity after a trial with 3 months of methotrexate or leflunomide, a 1-month trial of NSAID monotherapy, or a glucocorticoid injection.21 Anakinra is not FDA approved for the treatment of JIA.

**Costimulation Modulators**

Abatacept interferes with T-cell signaling, ultimately blocking T-cell activation and leading to anergy, or lack of response to an antigen.22 Abatacept is indicated as monotherapy or in combination with nonbiologic DMARDs following inadequate response to methotrexate or anti-TNF agents. Abatacept is FDA approved for the treatment of moderate to severe JIA; it is recommended as an option for patients who did not respond to an adequate trial of methotrexate, leflunomide, or anakinra.21

**Anti-CD20 Monoclonal Antibody**

Rituximab is a genetically engineered chimeric anti-CD20 monoclonal antibody that causes B-lymphocyte depletion in bone marrow and synovial tissue.22 The exact role of rituximab in RA is not clearly defined, but it is indicated for patients with moderate to severe active RA and a history of inadequate response to one or more TNF antagonist therapies. Patients with rheumatoid factor positive RA tend to respond more favorably to rituximab than patients with rheumatoid factor negative disease. Rituximab carries a black-box warning of fatal infusion reactions and severe mucocutaneous reactions, even though these events did not occur during the RA clinical trials. The benefits of rituximab must be tempered against the safety concerns reported with use of rituximab in the oncology setting. Rituximab may be used in the treatment of JIA, though its place in therapy is not clear and the medication is not FDA approved for this purpose.21

**Anti–interleukin-6 Receptor Antibody**

Interleukin-6 (IL-6) production is increased in patients with RA. High levels are indicative of joint damage and disease activity. In addition, IL-6 plays a significant role in the pathogenesis of anemia associated with RA.21 Tocilizumab, an anti–IL-6 receptor monoclonal antibody, inhibits the binding of IL-6 to the IL-6 receptor.22 Studies in patients not responding to methotrexate or TNF antagonists have demonstrated decreased disease activity and improved function and quality of life in patients with RA. In the 2012 recommendations, tocilizumab is considered after inadequate response or adverse event to anti-TNF agents, abatacept, or rituximab.21 Tocilizumab is FDA approved for the treatment of JIA; it is recommended for patients with inadequate response to glucocorticoid monotherapy, methotrexate, leflunomide, or anakinra.21

**Targeted Synthetic DMARDs (tsDMARDs)**

Tofacitinib selectively inhibits Janus kinases, with greatest affinity for JAK3.24 Tofacitinib is indicated for the treatment of moderate to severe RA as monotherapy or in combination with csDMARDs. Combination administration with boDMARDs is inappropriate due to increased safety concerns. One distinct advantage of tofacitinib over boDMARDs is the oral dosage form. The exact place in therapy of tofacitinib is in the management of RA is not yet known. Presently, it may be initiated if a patient does not have an adequate response to or is otherwise unable to receive csDMARDs or boDMARDs.24

**Selecting Disease-Modifying Therapy**

Table 57–4 highlights dosing, safety, monitoring, and patient counseling information for the common DMARDs. Developmental differences in the treatment of RA are tempered by the lack of long-term safety and efficacy data for boDMARDs. In addition, high

**Notes:**
- **Drug:**
  - Geriatric patients should receive the usual adult dose unless renal or hepatic impairment is present. Pediatric doses are provided for drugs that have FDA-approved indications for juvenile idiopathic arthritis (JIA).
  - To convert to SI units of mL/s, multiply by 0.0167.
  - CBC, complete blood count; CI, contraindicated; D, diarrhea; HA, headache; Hgb, hemoglobin; HTN, hypertension; IR, infusion reactions; ISR, injection site reactions; LFTs, liver function tests; MYL, myelosuppression (watch for fever, symptoms of infection, easy bruising, and bleeding); N, nausea; SC, subcutaneous injection; SOB, shortness of breath.
  - Data From Refs. 1, 2,19,22, and 25.
costs can be a deterrent to use. Cost analyses may indicate that the increased expenses associated with these boDMARDs are offset by the costs avoided for treatment of advanced RA.

**KEY CONCEPT** The risk of infection in patients treated with boDMARDs must be considered when selecting and monitoring therapy. Influencing the immune response to reduce symptoms of RA may influence the body’s response to pathogens. Of particular concern is use of TNF antagonists in patients with a history of tuberculosis exposure. TNF is important in the formation of granulomas that wall off tuberculosis infection. In theory, if TNF is inhibited, patients with latent tuberculosis may have a reactivated infection. Etanercept appears to have the lowest incidence rate of tuberculosis when compared with other TNF antagonists. Patients receiving any boDMARD agent should be screened for tuberculosis and other infections (hepatitis B, hepatitis C). Antituberculosis therapy should be initiated in patients with active or latent tuberculosis. Patients with active tuberculosis should receive the full course of antituberculosis treatment prior to initiating boDMARDs. If there is latent infection, boDMARD therapy may be initiated after at least 1 month of antituberculosis treatment. Patients with untreated hepatitis B should not receive boDMARDs. Etanercept may be a potential treatment option in patients with RA and concomitant hepatitis C. boDMARDs should not be initiated during an acute, serious infection and should be discontinued temporarily during times of infection. boDMARD therapy can be continued during nonserious infections. Concomitant use of two boDMARDs or tsDMARD plus boDMARD is contraindicated due to increased infection risk.

**Fertility, Pregnancy, and Fetal Development**

Women of childbearing potential should be counseled about the impact of antirheumatic drugs on fertility, pregnancy, fetal development, and lactation. Some women may experience a reduction in disease symptoms during pregnancy; however, many agents used to treat RA are known teratogens. In addition, some women may present with signs and symptoms of RA for the first time during the postpartum period. Women desiring motherhood must consult with their physicians to carefully plan for the pregnancy and reduce risks to the developing fetus. Treatment plans selected must also consider the potential effects on breast-feeding babies. Low-dose corticosteroids generally are safe and effective. Certain NSAIDs, hydroxychloroquine, and azathioprine may be considered in severe disease.

Methotrexate use (FDA Pregnancy Category X) is associated with spontaneous abortion, fetal myelosuppression, limb defects, and CNS abnormalities; therefore, pregnancy must be avoided. Methotrexate should be discontinued 3 months prior to attempting conception. Sulfasalazine, on the other hand, may be the drug of choice in women who are pregnant or planning to become pregnant due to its safety profile. There is limited data on safety of boDMARD use in pregnant women. Case reports of pregnancy during boDMARD therapy show no increased risk of fetal toxicity, but long-term data are needed. Based on available data, TNF antagonists are considered safe until the time of conception, and discontinuation during pregnancy is recommended. Rituximab should be discontinued 1 year prior to planned conception. Abatacept should be discontinued 10 weeks prior to planned conception.

Male patients with RA must receive counseling about the effects of certain medications on their fertility and potential harm to the fetus. It is difficult to establish causality between use of a medication by a male and the effect on fertility or fetal development; therefore, a conservative approach must be taken. Women of childbearing potential and their partners must be counseled to: (a) use proper birth control while undergoing treatment for RA, and (b) involve health care providers in discussions regarding family planning to carefully consider all treatment options.

### Patient Encounter, Part 2: Medical History, Physical Examination, and Laboratory Tests

| PMH: Hypertension (20 years), dyslipidemia (20 years), depression (5 years), diabetes (15 years), rheumatoid arthritis (10 years) |
| FH: Mother died age 70 from MI, also had RA, DM, HTN, dyslipidemia; father died age 82 from lymphoma |
| SH: Retired but owns a small business. She is a seamstress and relies heavily on her hands for the work of the business. She drinks alcohol occasionally and smokes a half pack of cigarettes daily. |
| Allergies: aspirin, penicillin |
| Meds: Lisinopril 10 mg once daily; hydrochlorothiazide 25 mg once daily; simvastatin 40 mg once daily; metformin 500 mg twice daily; paroxetine 20 mg once daily; methotrexate 15 mg orally once weekly; adalimumab 40 mg SC every other week; folic acid 1 mg daily; fish oil 1 g daily |
| Previous Meds: Etanercept, metoprolol, pravastatin |
| ROS: (+) Fatigue, (−) N/V/D, HA, SOB, chest pain, cough |
| PE: |
| VS: BP 186/92, P 86, RR 22, T 38.0°C (100.4°F); Ht 5’2” (157 cm), Wt 75 kg (165 lb) |
| Skin: Warm, dry |
| HEENT: NC/AT, PERRLA, TMIs intact |
| CV: RRR, normal S1 and S2, no m/r/g |
| Chest: CTA |
| Abd: Soft, NT/ND |
| Neuro: A&O × 3; CN II to XII intact |
| Ext: Bilateral tender and swollen PIPs and MCPs |
| Labs: ESR 65 mm/hour, RF (+), HLA-DR4 (+), ACPA (high +) |
| Synovial fluid analysis: Yellow, cloudy, decreased viscosity |
| Hand x-rays: Soft-tissue swelling, joint space narrowing, evidence of erosions |
| Disease Activity Score 28 (DAS-28): 6.63 |

How would you categorize this patient’s disease activity—low, moderate, or high? Why? How does this affect your treatment plan?

What nonpharmacologic and pharmacologic alternatives are appropriate for this patient?
Patient Encounter, Part 3: Creating a Care Plan

Based on the information available, create a care plan for this patient’s RA. The plan should include the following:
(a) A statement of the drug-related needs and/or problems
(b) A patient-specific detailed therapeutic plan (including specific medications and associated doses)
(c) Monitoring parameters to assess safety and efficacy

OUTCOME EVALUATION

- Rheumatologists rely on standardized criteria to assess treatment interventions through measurement of disease activity. The ACR uses criteria for improvement based on percentage improvement in tender and swollen joint count and the presence of at least three or more of the following measures: (a) pain, (b) patient global assessment, (c) physician global assessment, (d) self-assessed physical activity, and (e) acute-phase reactants. ACR20, ACR50, and ACR70 are common efficacy endpoints in clinical trials. The number corresponds with the percentage improvement. As drug development continues to evolve, the acceptable criteria for 20% improvement may be too low.
- Common tools to assess disease activity in patients with RA include Patient Activity Scale, Clinical Disease Activity Index, Simplified Disease Activity Index, and Disease Activity in 28 joints (DAS-28). Components involved in the calculation are the number of swollen and tender joints, ESR or CRP, and a subjective measure of the patient’s general health. A DAS-28 score of 3.2 or less indicates low disease activity, between 3.2 and 5.1 is considered moderate activity, and 5.1 or more is considered to be high activity. Remission as defined by DAS-28 is a score of less than 2.6.
- Physical disability from RA can be measured through the Stanford Health Assessment Questionnaire (HAQ). This patient self-assessment tool was developed to evaluate patient outcomes in five dimensions of chronic conditions: (a) disability, (b) discomfort, (c) drug adverse effects, (d) dollar costs, and (e) death. Clinicians and clinical studies in

Patient Care Process

Patient Assessment:
- Determine whether physical examination findings and patient-reported symptoms are consistent with RA. Evaluate the duration of symptoms and impact on daily living.
- Review the medical history. Does the patient have comorbidities that should also be addressed? Are features of poor prognosis present?
- Review laboratory test results to establish baseline hepatic function, renal function, and blood cell status.
- Conduct a medication history and review patient allergies. Are any of the medications causing the noted signs or symptoms?
- If the patient is already receiving pharmacotherapy for RA, assess efficacy, safety and patient adherence.
- Determine whether the patient has prescription coverage. If not, determine if the patient is eligible for prescription assistance programs.

Therapy Evaluation:
- Evaluate the presence of comorbidities and implement measures to control the increased risk.
- Cardiovascular: Keep doses of NSAIDs and glucocorticoids low; consider initiating folic acid, low-dose aspirin, and/or statin therapy, and encourage smokers to discontinue tobacco use. Screen and aggressively treat elevated blood pressure.
- Infection: Inform the patient to wash hands routinely, limit contact with individuals who are ill, and report signs and symptoms of infection immediately (eg, fever, weight loss, and night sweats).
- Malignancy: Have the patient report new signs and symptoms (eg, fever, chills, anorexia, and night sweats) immediately.
- Osteoporosis: Encourage the patient to ingest adequate amounts of calcium and vitamin D; consider initiating medications for osteoporosis if the patient is taking glucocorticoids chronically or has evidence of low bone mineral density.

Care Plan Development:
- Educate the patient on nonpharmacologic measures to improve symptoms.
- If the patient is newly diagnosed with RA, make sure s/he receives DMARD therapy immediately to minimize disease progression and joint destruction.
- Select DMARD therapy that is likely to be safe and effective. (see Figures 57–1 and 57–2)
- Ensure that drug doses are optimal (see Table 57–4).
- Screen for tuberculosis if initiation of a boDMARD is under consideration.
- Stress the importance of adherence with medications and laboratory monitoring.
- Assess the patient’s response to initiation of DMARD therapy after allowing adequate time for the medication to achieve its therapeutic effect.
- Determine whether any adverse reactions to antirheumatic medication are present.
- Monitor laboratory parameters to ensure patient safety and reduce the risk of adverse reactions.
- Longitudinally evaluate the patient’s clinical response to therapy and the impact on quality of life and mobility.
- Assess patient understanding of RA and medications they are taking. Provide additional education where appropriate.
Before starting treatment for RA, assess the subjective and objective evidence of disease. For joint findings, this includes the number of tender and swollen joints, pain, limitations on use, duration of morning stiffness, and presence of joint erosions. Systemic findings may include fatigue and the presence of extraarticular manifestations. Obtain laboratory measurements of CRP and ESR. The impact of the disease on quality of life and functional status is also important.

At follow-up visits, compare the patient’s status to baseline or previous visits using standardized criteria for improvement of disease activity and the influence on quality of life.

**KEY CONCEPT** In addition to designing an individualized therapeutic regimen to control the progression of RA, the clinician must evaluate the presence of comorbidities and implement measures to control the increased risk.

### Abbreviations Introduced in This Chapter

- ACPA: Anticitrullinated protein antibodies
- ACR: American College of Rheumatology
- boDMARD: Biological originator DMARD
- bsDMARD: Biosimilar DMARD
- COX-2: Cyclooxygenase-2
- CRP: C-reactive protein
- csDMARD: Conventional synthetic DMARD
- DAS: Disease Activity Score
- DMARD: Disease-modifying antirheumatic drug
- ESR: Erythrocyte sedimentation rate
- EULAR: European League against Rheumatism
- HAQ: Health Assessment Questionnaire
- HLA: Human leukocyte antigen
- IL: Interleukin
- JIA: Juvenile idiopathic arthritis
- MCP: Metacarpophalangeal joint
- MTP: Metatarsal or phalangeal joint
- NSAID: Nonsteroidal anti-inflammatory drug
- PIP: Proximal interphalangeal joint
- RA: Rheumatoid arthritis
- TNF: Tumor necrosis factor
- tsDMARD: Targeted synthetic DMARD

### REFERENCES

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms involved in the development of osteoarthritis (OA).
2. Identify risk factors associated with OA.
3. Recognize the clinical presentation of OA.
4. Determine the goals of therapy for individual patients with OA.
5. Formulate a rational nonpharmacologic plan for patients with OA.
6. Recommend a pharmacologic plan for treating OA, taking into consideration patient-specific factors.
7. Develop monitoring parameters to assess effectiveness and adverse effects of pharmacotherapy for OA.
8. Modify an unsuccessful treatment strategy for OA.
9. Deliver effective patient counseling, including lifestyle modifications and drug therapy, to facilitate effective and safe management of OA.

INTRODUCTION

Osteoarthritis (OA) is the most common form of arthritis and is strongly related to age. Its incidence and cost of care will increase dramatically in the coming years due to a burgeoning senior citizenry.

Weight-bearing joints (eg, hips and knees) are most susceptible, but non–weight-bearing joints, especially the hands, also may be involved. Because of its high prevalence and involvement of joints critical for daily functioning, the disease causes tremendous morbidity and financial burden. OA is the leading cause of chronic mobility disability and the most common reason for total-hip and total-knee replacement.

Epidemiology and Etiology

Globally, the age-standardized prevalence of knee and hip OA is at least 3.8% and 0.85%, respectively. High-income countries, which generally have older populations, have a higher prevalence than low-income countries. The National Arthritis Data Workgroup estimates that 27 million Americans have signs and symptoms of OA. Approximately 7% of US adults have daily symptomatic hand OA, whereas 6% and 3% report daily symptoms affecting the knees and hips, respectively. After age 60, 10% to 17% of persons report such symptoms.

The prevalence of OA is greater in women by 1.5- to 2-fold, and they tend to have more generalized disease. Women are also more likely to have inflammation of the proximal and distal interphalangeal joints of the hands, which manifest as Bouchard nodes and Heberden nodes, respectively. OA of the hip occurs more frequently in men.

The prevalence of OA in whites is similar to that in African Americans, but the latter may experience more severe and disabling disease. Persons of Chinese descent rarely have hip OA; they also are less likely to develop hand OA but more likely to develop knee OA.

PATHOPHYSIOLOGY

OA is characterized by damage to diarthrodial joints and joint structures (Figure 58–1). The pathophysiology is multifactorial and typified by progressive destruction of joint cartilage, erratic new bone formation, thickening of subchondral bone and the joint capsule, bony remodeling, development of osteophytes, variable degrees of mild synovitis, and other changes.

The earliest stages of OA are characterized by increasing water content and softening of cartilage in weight-bearing joints. As the disease progresses, proteoglycan content of cartilage declines, and eventually, cartilage becomes hypocellular. Protease enzymes proliferate before changes in cartilage, suggesting that catabolic proteinases play an important role in the initiation and progression of OA.

Subchondral bone undergoes metabolic changes, including increased bone turnover, that appear to be precursors to tissue destruction. The normally contiguous bony surface becomes fissured. Persistent use of the joint eventually results in loss of cartilage, permitting bone-to-bone contact that ultimately promotes thickening and eburnation of exposed bone. Microfractures may appear in subchondral bone, and osteonecrosis may develop beneath the surface especially in individuals with advanced disease.

New bone is formed haphazardly, leading to the formation of osteophytes that extend into the joint capsule and ligament attachments and may encroach on the joint space. Progressive loss of joint cartilage, subchondral damage, narrowing of joint spaces, and changes in the underlying bone and soft tissues may culminate in deformed, painful joints.
Classification

OA can be classified as primary (idiopathic) or secondary. Primary OA is the predominant form and occurs in the absence of a known precipitating event. Primary OA may assume a localized, generalized, or erosive pattern. Localized OA is distinguished from generalized disease by the number of sites involved. Erosive disease is characterized by an erosive pattern of bone destruction and marked proliferation of interphalangeal joints of the hands. Secondary OA results from congenital or developmental disorders or inflammatory, metabolic, or endocrine diseases.

Risk Factors

OA develops when systemic factors and biomechanical vulnerabilities combine. Systemic factors include age, gender, genetic predisposition, and nutritional status. Age is the strongest predictor of OA, although advanced age alone is insufficient to cause OA.

Joints exposed to biomechanical factors are at increased risk. Occupational and recreational activities involving repetitive motion or injury can provoke OA, although most daily activities do not produce enough joint trauma to cause OA, even after decades of repeated use. However, daily activities may lead to OA if a joint is susceptible because of previous injury, joint deformity, muscle weakness, or systemic factors. Heavy physical activity is a stronger predictor of subsequent OA than light-to-moderate activities, especially for older individuals, in whom the joint structure is less capable of coping with highly stressful activities. Obesity increases load-bearing stresses on hip and knee joints. The risk of OA increases by 10% for each kilogram of body weight above ideal body weight.

Clinical Presentation and Diagnosis

See the accompanying text box for the clinical presentation of OA. No laboratory tests are specific for diagnosing OA. The erythrocyte sedimentation rate (ESR) and hematologic and chemistry panels are usually unremarkable. Synovial fluid aspirated from an affected joint should be sterile, without crystals, and with a WBC count less than 1.5 × 10³/mm³ (1.5 × 10⁹/L).

Clinical Presentation of OA

General

- Patients usually are more than 50 years old.
- Presentation may range from asymptomatic to severe joint pain and stiffness with functional limitations.
- Joint involvement has an asymmetric local distribution without systemic manifestations.
- In contrast to some other arthritic conditions (e.g., rheumatoid arthritis, gout), inflammation usually is absent or mild and localized when present.

Symptoms

- The most common symptoms are joint pain, reduced range of motion, and brief joint stiffness after periods of inactivity.
- The cardinal symptoms are use-related joint pain, typically described as deep and aching in character, and stiffness. In advanced cases, pain may be present during rest.
- Weight-bearing joints may be unstable.
- Joint stiffness (“gelling”) abates with motion and recurs with rest.
- Joint stiffness generally lasts less than 30 minutes after periods of inactivity, limits the range of joint motion, impairs daily activities, and may be related to weather.

Signs

- One or more joints may be involved, usually in an asymmetric pattern.
- The following sites are most often involved in primary OA:
  - Distal interphalangeal finger joints (Heberden nodes)
  - Proximal interphalangeal finger joints (Bouchard nodes)
  - First carpometacarpal joint
  - Knees, hips, and cervicolumbar spine
  - Metatarsophalangeal joint of the great toe
- Joint examination may reveal local tenderness, bony proliferation, soft tissue swelling, crepitus, muscle atrophy, limited motion with passive/active movement, and effusion.
Radiographic changes are often absent in early OA. As the disease progresses, joint-space narrowing, subchondral bone sclerosis, and osteophytes may be detected. Gross joint deformity and joint effusions may occur in late severe OA.

**TREATMENT**

**Desired Outcomes**

**KEY CONCEPT** Goals of therapy include: (a) educating the patient and caregivers, (b) relieving pain, (c) maintaining or restoring mobility, (d) minimizing functional impairment and associated adverse outcomes (eg, falls), (e) preserving joint integrity, and (f) improving quality of life.

**General Approach to Treatment**

Treatment is individualized considering medical history, physical examination, radiographic findings, distribution and severity of joint involvement, and response to previous treatment. Comorbid diseases, concomitant medications, and allergies are integrated into a holistic treatment approach.

As shown in the treatment algorithm for OA (Figure 58–2), nonpharmacologic treatment is integral to achieving optimal outcomes. Pharmacologic therapy is an adjunctive measure to relieve pain; current treatments do not substantially modify the disease course. Surgical intervention generally is reserved for patients with advanced disease complicated by unremitting pain or severely compromised function.

**Nonpharmacologic Therapy**

**KEY CONCEPT** Nonpharmacologic therapy is the cornerstone of treatment: education, exercise, weight loss, and cognitive behavioral intervention are integral components.

Educational programs include systematic educational activities designed to improve health behaviors and health status, thereby slowing OA progression. The goal is to increase patient knowledge and self-confidence in adjusting daily activities in the face of evolving symptoms. Effective programs produce positive behavioral changes, decreased pain and disability, and improved functioning. In addition to physical outcomes, psychological outcomes such as depression, self-efficacy, and life satisfaction are positively influenced. Patients can be referred to the Arthritis Foundation (www.arthritis.org) for educational materials and information on support groups.

- Lifestyle modification should be encouraged for all patients at risk for and with established OA. Low-impact exercise is advisable for most patients, especially those with knee or hip OA. Aerobic exercise and strength-training programs improve functional capacity in older adults with OA. Stretching and strengthening exercises should target affected and vulnerable joints. Isokinetic and isotonic exercises performed at least three to four times weekly improve physical functioning and decrease disability, pain, and analgesic use.

- Obesity’s association with both the onset and progression of OA make weight loss a pivotal treatment goal in overweight and obese patients. Women who reduce body weight by 5 kg (11 lb) can cut their risk of developing OA in half. Moreover, symptomatic relief and improved quality of life occur in people with knee OA who lose weight. Weight loss should be pursued through a combination of dietary modification and increased physical activity (see Chapter 102, Overweight and Obesity). The patient’s physical capabilities should be considered when implementing an exercise program.

- Application of heat or cold to involved joints improves range of motion, reduces pain, and decreases muscle spasms. Applications of heat include warm baths or warm water soaks. Heating pads should be used with caution, especially in the elderly, and patients must be warned of the potential for burns if used inappropriately.

- Referral to a physical or occupational therapist may be helpful, particularly in patients with functional disabilities. Physical therapy is tailored to the patient and may include assessment of muscle strength, joint stability, and mobility; use of heat (especially prior to episodes of increased physical activity); structured exercise regimens; and assistive devices such as canes, crutches, and walkers. The occupational therapist ensures optimal joint protection and function, energy conservation, and advice on use of splints and other assistive devices.

**Pharmacologic Therapy**

Simple analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are first-line agents for treating OA (Table 58–1).

**Acetaminophen**

Acetaminophen is a centrally acting analgesic that inhibits prostaglandin production in the brain and spinal cord. **KEY CONCEPT** Acetaminophen is an effective and inexpensive analgesic with a favorable risk–benefit profile. For treatment of mild-to-moderate pain, acetaminophen should be tried initially at an adequate dose and duration before considering an NSAID. Acetaminophen is generally considered to be as effective as NSAIDs for mild-to-moderate joint pain with a more favorable adverse effect profile.

- Acetaminophen should be administered initially on an as-needed basis in daily doses up to 4 g. Single doses should not exceed 1 g. Some patients may require scheduled dosing to achieve adequate pain relief. Periodic assessment of pain control should be performed to maintain the lowest effective dose. A common reason for an inadequate response to acetaminophen is failure...

CrCl, creatinine clearance.

<sup>a</sup>Serum salicylate levels should be monitored for doses greater than 3 g/day.

<sup>b</sup>Total daily dose of diclofenac 1% gel should not exceed 32 g for all affected joints.

<sup>c</sup>Celecoxib is a substrate for CYP2C9, and a 50% reduction in the initial dose should be considered in known or suspected poor metabolizers.
Inhibition of the COX-1 enzyme is thought to result in analgesic and anti-inflammatory effects. All NSAIDs inhibit both the COX-1 and COX-2 enzyme isoforms, but nonselective NSAIDs (eg, ibuprofen, diclofenac, naproxen) are not particularly selective for one isoform over the other, whereas COX-2 inhibitors (ie, celecoxib) preferentially inhibit the COX-2 isoform.

Nonsteroidal Anti-inflammatory Drugs

Prostaglandins play an important role in the function of several organ systems. These compounds are synthesized via the interaction of two isoforms of the cyclooxygenase enzyme (COX-1 and COX-2) with their substrate, arachidonic acid.

The COX-1 enzyme is expressed constitutively in various body tissues (eg, gastric mucosa, kidney, and platelets). Prostaglandins produced by the actions of the COX-1 enzyme in the gastrointestinal (GI) tract preserve the integrity of the GI mucosa by increasing mucous and bicarbonate secretion, maintaining mucosal blood flow, and decreasing gastric acid secretion. Prostaglandins associated with COX-1 also promote normal platelet activity and function. In the kidney, COX-1–mediated prostaglandins dilate the afferent arteriole, thereby maintaining intraglomerular pressure and glomerular filtration rate when renal blood flow is reduced.

In contrast, the COX-2 enzyme is normally undetectable in most tissues, but its expression can be induced rapidly in the presence of inflammation and local tissue injury. This change leads to the synthesis of prostaglandins involved in pain and inflammation. Consequently, blocking the COX-2 enzyme is thought to result in analgesic and anti-inflammatory effects. All NSAIDs inhibit both the COX-1 and COX-2 enzyme isoforms, but nonselective NSAIDs (eg, ibuprofen, diclofenac, naproxen) are not particularly selective for one isoform over the other, whereas COX-2 inhibitors (ie, celecoxib) preferentially inhibit the COX-2 isoform.

NSAIDs are a reasonable first-line therapy in patients with moderate-to-severe OA; or, as adjunctive or alternative therapy when acetaminophen fails to provide an acceptable analgesic response. NSAIDs significantly reduce pain and improve functioning in patients with OA, although individual responses can vary widely. Some clinicians recommend NSAIDs over acetaminophen for the initial treatment of severe pain or when signs and symptoms of inflammation are present. Results from comparative trials of acetaminophen and NSAIDs have been equivocal, but consensus guidelines support the use of NSAIDs as an alternative to acetaminophen if clinical features of peripheral inflammation or severe pain are present. Unfortunately, no validated mechanism exists to identify patients who are more likely to respond to NSAIDs than acetaminophen. The route of administration (ie, oral or topical) should be based on affected joint(s), patient preference, ability to administer, and an assessment of risk for adverse effects of systemic NSAIDs.

Topical administration of NSAIDs minimizes systemic exposure while providing pain relief comparable to that of oral NSAIDs, but topical NSAIDs are only appropriate for patients with OA of superficial joints, including hands, wrists, elbows, knees, ankles, and feet. Currently, the only commercially available topical NSAID in the United States is diclofenac, which comes in a variety of preparations, including a solution, gel, and topical patch. These products all decrease pain and improve joint function with no demonstrated superiority for any one product over others.

Systemic absorption of topical diclofenac is significantly less than that of oral diclofenac. Thus, GI, cardiovascular, and renal adverse effects are rare and similar in incidence to placebo with proper administration. The most common adverse effects include application site dermatitis, pruritus, and phototoxicity.

For patients with OA that affects deeper joints (eg, hip), or who have not achieved an adequate response to topical NSAIDs, an oral NSAID should be considered. At equipotent doses, the analgesic and anti-inflammatory activity of all oral NSAIDs, including COX-2–selective inhibitors, are similar. The selection of a specific oral NSAID should be based on patient preference, previous response, tolerability, dosing frequency, cost, and considering underlying GI and cardiovascular risk. Some patients respond to one NSAID better than to another. If an insufficient response is achieved with one NSAID, another agent should be tried. Pain relief occurs rapidly (within hours) with these agents, but anti-inflammatory benefits are not realized until after 2 to 3 weeks of continuous therapy. This period is the minimal duration that should be considered an adequate NSAID trial.

All NSAIDs are associated with adverse GI, renal, hepatic, cardiovascular, CNS, and blood pressure effects, particularly in the elderly. Inhibition of the COX-1 enzyme is thought to be responsible primarily for the adverse effects on the gastric mucosa, kidney, and platelets. Direct irritant effects also may contribute to adverse GI events. Minor GI complaints, including nausea, dyspepsia, anorexia, abdominal pain, flatulence, and diarrhea, are reported by 10% to 60% of patients treated with nonselective NSAIDs. Asymptomatic gastric and duodenal mucosal ulceration can be detected in 15% to 45% of patients.23 Perforation, gastric outlet obstruction, and GI bleeding are the most severe complications and occur in 1.5% to 4% of patients annually.

COX-2 inhibitors should be reserved for patients at high risk for GI complications and low risk for cardiovascular events (Table 58–2).23 Several risk factors predict a greater likelihood of GI complications in NSAID-treated patients (see Chapter 18, Peptic Ulcer Disease). Detecting high-risk patients based on symptoms alone is impractical because the presence of symptoms and actual gastroduodenal damage are poorly correlated. For patients at particularly high GI risk (eg, previous history of NSAID-induced GI bleed), a selective COX-2 inhibitor combined with a proton pump inhibitor reduces risk for GI bleeds compared to a selective COX-2 inhibitor alone, which in turn has lower risk for GI bleeds compared to a nonselective NSAID combined with a proton pump inhibitor.24–26
COX-2, selective cyclooxygenase-2 inhibitor; CV, cardiovascular; NS-NSAID, nonselective nonsteroidal anti-inflammatory drug.

aLow-dose aspirin indicated for prevention of cardiovascular event.
bHistory of complicated ulcer or > 2 of the following: Age > 65 years, high dose NSAID, prior complicated ulcer, and current use of aspirin, corticosteroids, or anticoagulants.
cNaproxen may be considered initially due to potentially lower CV risk compared with other NS-NSAIDs.
dGastroprotection with either a proton pump inhibitor (preferred) or misoprostol.
eA COX-2 inhibitor + gastroprotection can be recommended for patients at very high GI risk (eg, previous upper GI bleed attributable to NS-NSAID therapy).

Although selective COX-2 inhibitors reduce GI events, these agents have been associated with increased risk of cardiovascular events relative to many nonselective NSAIDs. The pharmacologic basis for this finding is not fully understood, but multiple factors may be involved, including the degree of COX-2 selectivity, dosage and dosing schedule, and potency of agents. Other mechanisms for increasing cardiovascular risk have been proposed for individual agents. Large scale meta-analyses suggest that COX-2 inhibitors (including celecoxib) and, to a lesser extent, diclofenac and ibuprofen, have the strongest association with major vascular events (eg, stroke, myocardial infarction). In patients at risk for GI events and cardiovascular disease and requiring oral NSAID therapy, a nonselective NSAID plus a proton pump inhibitor is a reasonable option. Naproxen appears to have the lowest incremental cardiovascular risk of the nonselective NSAIDs and should generally be considered first in such patients. Concomitant use of low-dose aspirin mitigates some of the increased cardiovascular risk of selective COX-2 inhibitors but also obliterates the GI safety of COX-2 selectivity. Patients treated with a selective COX-2 inhibitor plus aspirin experience GI complications at a rate commensurate with that of patients given a nonselective NSAID. Use of NSAIDs that have more relative COX-2 inhibition but are not selective COX-2 inhibitors (eg, meloxicam) to avoid cardiovascular concerns with selective COX-2 inhibitors may not be justified because neither GI nor cardiovascular safety is optimized.

All NSAIDs can cause renal insufficiency when administered to patients whose renal function depends on prostaglandins. Patients with chronic renal insufficiency or left ventricular dysfunction, the elderly, and those receiving diuretics or drugs that interfere with the renin–angiotensin system are particularly susceptible. These effects may result in decreased glomerular filtration, hyperkalemia, and sodium and water retention. Therefore, both nonselective NSAIDs and selective COX-2 inhibitors should be used with caution in patients with hypertension, heart failure, or chronic renal insufficiency. NSAIDs rarely cause tubulointerstitial nephropathy and renal papillary necrosis.

Caution is warranted in pregnant women and women of childbearing potential because the risk of bleeding may be increased if the fetus is subjected to the antiplatelet activity of NSAIDs. Most NSAIDs are Category C before 30 weeks of gestation. After that, all NSAIDs should be avoided because they may promote premature closure of the ductus arteriosus in the fetus.

Nonselective NSAIDs and selective COX-2 inhibitors are prone to drug interactions due to high protein binding, detrimental renal effects, and antiplatelet activity. Interactions are encountered frequently with aspirin, warfarin, oral hypoglycemics, antihypertensives (ie, angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], β-blockers, diuretics), and lithium. When potential interactions are present, vigilant monitoring is warranted for therapeutic efficacy (eg, NSAIDs blunt the antihypertensive efficacy of diuretics) and adverse effects (eg, NSAIDs increase the risk of bleeding in anticoagulated patients).

> **Tramadol**

Use of opioid analgesics may be warranted when pain is unresponsive to other pharmacologic agents or when such agents are contraindicated. Tramadol is an oral, centrally acting synthetic opioid analgesic that also weakly inhibits the reuptake of serotonin and norepinephrine. Tramadol effectively treats moderate pain but is devoid of anti-inflammatory activity. Tramadol is scheduled as a controlled substance (C-IV) in the United States due to its comparatively low abuse potential.

Tramadol is a reasonable option for patients with contraindications to NSAIDs or in those who have failed to respond to other oral therapies. The addition of tramadol to NSAIDs or acetaminophen may augment the analgesic effects of a failing regimen, thereby securing sufficient pain relief in some patients. Moreover, concomitant tramadol may permit the use of lower NSAID doses. However, the increased risk for side effects associated with tramadol may offset the benefits. Dizziness, vertigo, nausea, vomiting, constipation, and lethargy are all relatively common adverse events. These effects are more pronounced for several days after initiation and following upward dose titration. Seizures have been reported rarely; the risk is dose-related and appears to increase with concomitant use of antidepressants, such as tricyclic antidepressants or selective serotonin reuptake inhibitors. Tramadol should be avoided in patients receiving monoamine oxidase (MAO) inhibitors due to the potential for serotonin syndrome.

> **Other Opioid Analgesics**

Opioids decrease pain, improve sleep patterns, and increase functioning in patients with OA who are unresponsive to nonpharmacologic therapy and nonopioid analgesics. Evidence suggests that patients can achieve satisfactory analgesia by using nonescalating doses of opioids with minimal risk of addiction. However, clinically significant improvement in pain that is nonresponsive to NSAIDs has only been demonstrated with stronger opioids. Oxycodeone is the most extensively studied of the opioids recommended for OA. However, other agents such as morphine, hydromorphone, methadone, and transdermal fentanyl are also effective.

Opioid analgesics should be reserved for patients who experience pain severe enough to require opioid treatment for which alternative treatment options are inadequate. Opioids also may be appropriate in patients with severe OA and conditions that preclude the use of NSAIDs, such as renal failure, heart failure, or anticoagulation.
Opioids should be initiated at low doses in combination with acetaminophen or an NSAID when possible. Combining opioids with other analgesics reduces the opioid requirement, thereby minimizing adverse events. However, use of combination opioid products containing acetaminophen should be accompanied by clear instructions to limit additional over-the-counter acetaminophen use. Conservative initial doses of opioids are warranted, with the dose titrated to the lowest dose achieving an adequate response while minimizing adverse effects. Even with these conservative strategies, adverse effects are common. In clinical trials, more than 80% of opioid-treated patients experienced at least one adverse event, compared with approximately 50% of placebo-treated patients. Common or serious adverse effects include nausea, constipation, sedation, and respiratory depression (see Chapter 34, Pain Management).

If opioid therapy is considered, there should be an initial comprehensive medical history and physical examination, documentation that nonopioid therapy has failed, clearly defined treatment goals, an understanding between the provider and the patient of the true benefits and risks of long-term opioids, use of a single provider and pharmacy whenever possible, and comprehensive follow-up.

**Duloxetine**

Duloxetine, a serotonin/norepinephrine reuptake inhibitor (SNRI), is effective as adjunctive therapy for knee OA in patients achieving a suboptimal response to acetaminophen or oral NSAIDs alone. Benefits typically are observed only after several weeks of therapy with moderate doses (ie, 60 mg/day); larger doses do not provide additional benefit. Duloxetine may be the preferred adjunctive treatment in patients experiencing concurrent neuropathic and musculoskeletal pain. The most common adverse events are nausea, dry mouth, somnolence, constipation, decreased appetite, and hyperhidrosis. Concomitant use with tramadol should be done cautiously owing to an increased risk of serotonin syndrome.

**Intraarticular Therapy**

Intraarticular therapies represent an alternative to oral agents for treatment of joint pain. This modality is usually reserved for patients unresponsive to other treatments because of the relative invasiveness of intraarticular injections compared with oral and topical drugs, the small risk of infection, and the cost of the procedure.

**Corticosteroids**

Use of systemic corticosteroids is discouraged in patients with OA. However, in a subset of patients with an inflammatory component or knee effusion, intraarticular corticosteroids can be useful as monotherapy or as an adjunct to analgesics. Corticosteroids with reduced solubility, such as methylprednisolone and triamcinolone, are usually preferred. The affected joint can be aspirated and subsequently injected with the corticosteroid. The aspirate should be examined for the presence of crystal formation and infection. Pain relief begins within days after the injection but may wane beyond 3 weeks. Injections should be done as infrequently as possible to avoid joint damage. Specifically, a single joint should not be injected more than three to five times per year to reduce the risk of corticosteroid-induced cartilage and joint damage. Given that the recommended dosing interval greatly exceeds the typical duration of action, these agents are rarely effective as monotherapy for chronic treatment of OA.

The crystalline nature of corticosteroid suspensions can provoke a postinjection flare in some patients. The ensuing flare mimics the flare of arthritis and inflammation that accompanies infection. Cold compresses and analgesics are recommended to treat symptoms in affected patients.

**Hyaluronic Acid**

The mechanism of action of hyaluronic acid is not fully understood. Healthy cartilage and synovial fluid are replete with hyaluronic acid, a viscous substance believed to facilitate lubrication and shock absorbency under varying conditions of load bearing. Patients with OA demonstrate an absolute and functional decline in hyaluronic acid; thus, exogenous administration is referred to as viscosupplementation.

Improvement in pain and joint function following intraarticular hyaluronic acid injections has been evaluated frequently in clinical trials, most of which were of low quality. Evidence is conflicting, but these agents appear to promote only modest improvements in pain and joint function. Consequently, hyaluronic acid is generally not recommended in current treatment guidelines.

Several formulations of hyaluronic acid are available in the United States for treatment of knee OA. Administration typically consists of weekly injections for 3 to 5 weeks, depending on the specific product. Most injections are well tolerated, although some patients may report local reactions. Rarely, postinjection flares and anaphylaxis have been reported. Intra-articular injection is associated with a low risk of infection (approximately 1 joint in 50,000 injections). Patients should be counseled to minimize activity and stress on the joint for several days after each injection.

**Over-the-Counter Agents**

**Glucosamine and Chondroitin**

Glucosamine is believed to function as a "chondroprotective" agent, stimulating the cartilage matrix and protecting against oxidative chemical damage. Chondroitin, often administered in conjunction with glucosamine, is thought to inhibit degradative enzymes and serve as a substrate for the production of proteoglycans. The highest quality evidence to date suggests no clinically important difference in efficacy between glucosamine, chondroitin, their combination, or placebo in patients with knee OA. Consequently, these products, used alone or in combination, are generally not recommended.

These agents are loosely regulated in the United States as dietary supplements, product standards are inconsistent, and the constituents are not validated by any regulatory agency. The use of glucosamine (derived from crab, lobster, or shrimp shells) and/or chondroitin (derived from cattle or shark cartilage) may warrant caution in patients with shellfish allergies, but preliminary evidence suggests little drug–allergy interaction. Additionally, glucosamine may alter cellular glucose uptake, thus elevating blood glucose levels in diabetic patients. Because the clinical significance of this is unclear, blood glucose levels in diabetic patients should be monitored closely after glucosamine initiation or dosage adjustments.

**Other Topical Agents**

There are limited data to support the use of salicylate-containing rubefacients (eg, methyl salicylate and trolamine salicylate) or other counterirritants (eg, menthol, camphor, and methyl nicotinate) in OA. See Chapter 60 (Musculoskeletal Disorders) for more information on these products when used for musculoskeletal disorders.

Capsaicin achieves pain relief by depleting substance P from sensory neurons in the spine, thereby decreasing pain transmission. Capsaicin is not effective for acute pain; it may take up to 2 weeks of daily administration to achieve pain relief. Capsaicin may provide the greatest benefit to painful superficial joints (eg, hand OA). The lower concentration (0.025%) is typically
In patients taking oral NSAIDs, monitor for increases in

Incorporate other measures to track disease progress. Use

At baseline, quantify pain using a visual analogue scale, assess

Perform stool guaiac in patients taking oral NSAIDs when

Monitor for drug interactions, including alcohol, at every visit.

Ask patients if they are experiencing side effects or other

49 Evaluate serum creatinine, complete blood count, and serum

- OUTCOME EVALUATION

- At baseline, quantify pain using a visual analogue scale, assess range of motion of affected joints, and identify activities of daily living that are impaired.

- In patients treated with acetylsalicylic acid or oral NSAIDs, assess pain control after 2 to 3 weeks. It may take longer for the full anti-inflammatory effect of NSAIDs to occur.

**Surgery**

Surgery generally is reserved for patients who fail to respond to medical therapy and have progressive limitations in activities of daily living (ADL). In joint replacement surgery (arthroplasty), the damaged joint surfaces are replaced with metal or plastic prosthetic devices. Hip and knee joints are most commonly replaced, but arthroplasty may also be performed on shoulders, elbows, fingers, and ankles. Most patients achieve significant pain relief and functional restoration after arthroplasty, and it is a reasonable option in carefully selected refractory patients.

Surgical debridement may be performed arthroscopically. With this procedure, a tiny video camera is inserted into the affected joint through a small incision, and the surgeon removes torn cartilage or other debris from the joint. The long-term benefits of arthroscopic surgery for OA are unclear, and it may be no better than optimized physical and medical therapy.46

**OUTCOME EVALUATION**

- At baseline, quantify pain using a visual analogue scale, assess range of motion of affected joints, and identify activities of daily living that are impaired.

- In patients treated with acetylsalicylic acid or oral NSAIDs, assess pain control after 2 to 3 weeks. It may take longer for the full anti-inflammatory effect of NSAIDs to occur.

**Patient Encounter, Part 3: Creating a Care Plan**

Based on the available information, create a care plan for this patient’s OA. The plan should include:

(a) A statement of the drug-related needs and/or problems

(b) An individualized, detailed therapeutic plan

(c) A plan for follow-up monitoring to document the patient’s response and identify adverse reactions

- Incorporate other measures to track disease progress. Use radiography to assess severity of joint destruction, determine 50-ft (~15 m) walking time and grip strength, and administer the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) and the Stanford Health Assessment Questionnaire, where appropriate, to assess activities of daily living.

- Ask patients if they are experiencing side effects or other problems with their medications and respond with more specific questions.

- In patients taking oral NSAIDs, monitor for increases in blood pressure, weight gain, edema, skin rash, and CNS adverse effects such as headaches and drowsiness.

- Evaluate serum creatinine, complete blood count, and serum transaminases at baseline and at every 6 to 12 months in patients treated with oral NSAIDs or acetylsalicylic acid.

- Perform stool guaiac in patients taking oral NSAIDs when clinically indicated.

- Monitor for drug interactions, including alcohol, at every visit.

**Patient Encounter, Part 2: Medical History, Physical Examination, and Diagnostic Tests**

**PMH:** Obesity (BMI 30 kg/m²), HTN for 24 years, dyslipidemia, nonischemic cardiomyopathy, COPD, heat failure with reduced ejection fraction

**PSH:** Torn meniscus s/p repair on right knee 20 years ago

**FH:** Father had OA of the hip and knee; mother died of MI at age 68

**SH:** Retired clerk. Denies alcohol use; denies illicit drug use; smoked two packs of cigarettes per day for 35 years but quit 3 years ago

**Allergies:** NKDA; shellfish allergy

**Meds:** Lisinopril 40 mg once daily; metoprolol succinate 200 mg once daily; furosemide 20 mg once daily; spiranorlactone 25 mg once daily; atorvastatin 20 mg once daily; enteric-coated aspirin 81 mg once daily; tiotropium 18 mcg once daily; albuterol 90 mcg as needed for wheezing/shortness of breath; acetylsalicylic acid 500 mg one to two tablets two to four times per day as needed for pain

**ROS:** (+) SOB on exertion, right knee pain 5 out of 10 with movement

**PE:**

**VS:** BP 119/72 mm Hg, Pulse 61 beats/min, RR 16 breaths/min, T 98.6°F (37.0°C)

**HEENT:** NC/AT, PERRLA, TMs intact

**CV:** RRR, normal S₁ and S₂, no m/r/g

**Skin:** Warm, dry, cracked skin on feet bilaterally

**Knee x-rays:** Right knee shows joint space narrowing, minor osteophyte formation, and subchondral bone sclerosis

**What clinical parameters are consistent with a diagnosis of OA?**

**What are the treatment goals for this patient?**

**What nonpharmacologic options are available to treat this patient?**

**What pharmacologic options are available to treat this patient?**

**What factors are important to consider when selecting medications for this patient?**
Patient Care Process

Patient Assessment:
- Determine whether the patient’s symptoms are consistent with OA. Review the medical history to determine whether other rheumatologic diseases may be involved.
- Assess symptoms to determine whether pain warrants additional attention. Does the pain affect quality of life or interfere with activities of daily living?
- Assess radiographs for diagnosis and disease severity (joint-space narrowing, subchondral bone sclerosis, osteophyte formation, joint deformity, joint effusion).
- Consider obtaining laboratory tests depending on degree of clinical suspicion for inflammatory etiology (eg, ESR, CRP, rheumatoid factor, ANA).

Therapy Evaluation:
- Obtain a thorough history of previous device and drug use, including prescription drugs, over-the-counter drugs, and dietary supplements.
- Assess the effectiveness of any current or previous pharmacotherapy, including dose, frequency, and duration to determine whether an adequate trial was given.

Care Plan Development:
- Formulate a plan for lifestyle modifications and alteration/addition of pharmacotherapy that considers risks, benefits, and patient preference given the patient’s medical history, concomitant medications, and previous successful/failed OA therapies.
- Address patient concerns related to OA, its treatment, with special focus on the potential adverse effects of medications.
- Emphasize the value of adherence to medication regimens and lifestyle modifications. Facilitate adherence by implementing medication regimens and lifestyle plans that are simple and consistent with the patient’s lifestyle.

Follow-Up Evaluation:
- Schedule follow-up to assess the effectiveness of therapy and associated adverse effects; the specific time frame depends on patient factors and the treatment regimen chosen. If laboratory tests (eg, renal function) are required for monitoring drug therapy, provide the patient with an order for the laboratory tests and instructions to complete them prior to the next appointment.
- Document whether the patient has had improvements in pain, quality-of-life measures, mobility and functioning, ability to perform activities of daily living, and well-being.
- Ascertain new OTC medication use; for patients taking acetaminophen, pay particular attention to OTC sources of acetaminophen.
- Evaluate for the presence of adverse drug reactions, drug hypersensitivity, and potential drug interactions.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying gout and hyperuricemia.
2. Recognize major risk factors for developing gout in a given person.
3. Assess the signs and symptoms of an acute gout attack.
4. List the treatment goals for a patient with gout.
5. Develop a pharmacotherapeutic plan for a patient with acute gouty arthritis that includes individualized drug selection and monitoring for efficacy and safety.
6. Identify patients for whom prophylactic urate lowering therapy for gout and hyperuricemia is warranted.
7. Select an appropriate drug to reduce serum uric acid (SUA) levels in patients with gout, and outline a plan for monitoring efficacy and toxicity.
8. Formulate appropriate educational information for a patient on lifestyle modifications to help prevent gouty arthritis attacks.

INTRODUCTION

Gout is an inflammatory condition of the arthritis-type that results from deposition of uric acid crystals in joint spaces, leading to an inflammatory reaction that causes intense pain, erythema, and joint swelling. It is associated with hyperuricemia, defined as a serum uric acid (SUA) level of 6.8 mg/dL (404 μmol/L) or greater, but not all patients with hyperuricemia demonstrate symptoms.¹ There are presently three published guidelines that provide clinical recommendations for management of patients with gout.²⁻⁷ This chapter will focus primarily on recommendations of the American College of Rheumatology (ACR).⁵⁻⁷

EPIDEMIOLOGY AND ETIOLOGY

Gout is the most common inflammatory arthritis in men, with a male:female incidence of about 4:1; it affects over 3% of US adults.¹,⁸ The National Health and Nutrition Examination Survey (NHANES) 2007–2008 estimated the prevalence of gout among US adults to be 8.3 million.² Furthermore, the annual US incidence is approximately 62 cases per 100,000 persons and rising.¹ The incidence increases with age and is rising in part due to a larger number of patients with risk factors for gout.¹⁰

PATHOPHYSIOLOGY

Gout is caused by an abnormality in uric acid metabolism. Uric acid is a waste product of the breakdown of purines contained in the DNA of degraded body cells and dietary protein. Uric acid is water soluble and excreted primarily by the kidneys, although some is broken down by colonic bacteria and excreted via the gastrointestinal (GI) tract.¹¹

The solubility of uric acid depends on concentration and temperature. At high serum concentrations, lower body temperature causes the precipitation of monosodium urate (MSU) crystals. Collections of these crystals (called microtophi) can form in joint spaces in the distal extremities. Larger tophi may take 10 years or longer to develop.

Gouty arthritis can also result from systemic activation of proinflammatory mediators, including tumor necrosis factor α (TNF-α), interleukin 1 (IL-1), and IL-8. Activation of these mediators signals chemotactic movement of neutrophils into the joint space that ingest MSU crystals via phagocytosis. These neutrophils then are lysed and release proteolytic enzymes that trigger the clinical manifestations of an acute gout attack such as pain and swelling. These inflammatory mechanisms in gout, especially in untreated disease, can lead to cartilage and joint destruction.

The increased SUA involves either the underexcretion of uric acid (80% of patients) or its overproduction. The cause of overproduction or underexcretion of uric acid in most gout patients is unknown; this is referred to as primary gout.¹

The reference range for SUA is 3.6 to 8.3 mg/dL (214–494 μmol/L). The risk of gout increases as the SUA concentration increases. Approximately 30% of patients with levels greater than 10 mg/dL (595 μmol/L) develop symptoms of gout within 5 years.¹³ However, most patients with hyperuricemia are asymptomatic.

Dietary risk factors involve ingestion of animal purines, fructose, and alcohol (especially beer). Patients experiencing...

Long-term consequences of gout and hyperuricemia include joint destruction, tophi, nephrolithiasis, and nephropathy.

Clinical Presentation and Diagnosis

Refer to the accompanying box for the clinical presentation of acute gouty arthritis.

Diagnosis

A presumptive diagnosis is often based on presenting symptoms and may be confirmed later with laboratory and other diagnostic tests. Severe joint pain, swelling, tenderness, and erythema that rapidly peak are highly suggestive of, but not specific for, gout. For example, it is essential to distinguish between gout and septic arthritis to provide appropriate treatment. Gout is a reasonably accurate clinical diagnosis in patients with recurrent podagra and hyperuricemia.

The serum uric acid level often is elevated but may be normal during an acute attack. In addition, an elevated SUA alone is not diagnostic for gout. The peripheral WBC count may be only mildly elevated. Other laboratory markers of inflammation (eg, increased erythrocyte sedimentation rate) are often present.

Aspiration of affected joint fluid or a tophus is essential for a definitive diagnosis. Needle-shaped negatively birefringent MSU crystals in the aspirate confirm the diagnosis (Figure 59–1). Joint fluid may also have an elevated white blood cell (WBC) count with neutrophils predominating. If infection is suspected, it is imperative to obtain the appropriate diagnosis and treatment.

Radiographs of affected joints may have characteristic cystic changes, punched-out lytic lesions with overhanging bony edges, and soft-tissue calcified masses. These signs may also appear in other arthropathies and are generally not apparent with the first acute gout attack. Therefore, radiographs are often reserved for patients with long-standing disease.

Although rarely performed, a 24-hour urine collection can be obtained to determine whether the patient is an overproducer or an underexcretor of uric acid. Individuals who excrete more than 800 mg (4.8 mmol) of uric acid in this collection are considered overproducers. Patients with hyperuricemia who excrete less than 600 mg/day (3.6 mmol/day) are classified as underexcretors of uric acid.

Key Concept

Some drugs can cause hyperuricemia and precipitate gout, such as thiazide and loop diuretics, niacin, pyrazinamide, calcineurin inhibitors, and, occasionally, aspirin. In most cases, these drugs block uric acid secretion in the kidney.

The effect of aspirin on uric acid is dose dependent. At very high doses (eg, 4000 mg/day), aspirin blocks uric acid reabsorption by the kidneys, increasing uric acid excretion. Smaller aspirin doses inhibit uric acid excretion and can elevate serum uric acid levels. The very low aspirin doses (75–81 mg/day) used for heart attack or stroke prevention do not substantially alter uric acid levels. For these reasons, aspirin in analgesic doses (325–650 mg several times per day) should be avoided. However, patients with hyperuricemia or gout and cardiovascular risk factors should continue low-dose aspirin for cardiovascular prophylaxis because the cardiovascular benefit outweighs the minimal effect on serum urate.

Key Concept

Long-term consequences of gout and hyperuricemia include joint destruction, tophi, nephrolithiasis, and nephropathy.

Clinical Presentation of Acute Gouty Arthritis

General

• Acute inflammatory monoarthritis.
• Patients are usually in acute distress.

Symptoms

• There is severe pain and swelling in the affected joint(s).
• Symptoms reach maximal intensity within 6 to 12 hours.
• The attack is usually monoarticular; the most common site is the metatarsophalangeal joint.
• In elderly patients, gouty attacks may be atypical with insidious and polyarticular onset, often involving hand or wrist joints.

Signs

• Affected joint(s) are warm, erythematous, and swollen.
• Mild fever may be present.
• Tophi (usually on hands, wrists, elbows, or knees) may be present in chronic, severe disease.
Patient Encounter, Part 1

A 47-year-old obese Caucasian man presents to the emergency department with a 16-hour history of rapidly escalating excruciating pain (over 8 hours) in his left big toe unrelated to trauma. On examination, his left great toe is red, swollen, tender, and warm to the touch. During the initial patient interview, he states that this is the second time he has experienced this type of throbbing pain in his toe (last episode occurred 2 months ago and was successfully treated). He rates the pain as 10/10 (10 being the worst pain he has ever experienced). He is an unemployed, single father who did not graduate from high school. He has two young children and is concerned that he will be unable to find work and care for his children if this pain continues to occur frequently.

What information is suggestive of acute gouty arthritis?
What additional information is necessary to differentiate gout from other joint abnormalities?
What additional information do you need before creating a treatment plan for this patient?
What are aspects to consider when providing care for a patient who is unemployed and with limited formal education?

TREATMENT OF ACUTE GOUTY ARTHRITIS

**KEY CONCEPT** Treatment of gout involves: (a) acute relief of a gouty arthritis attack with topical application of ice and drug therapy commonly including NSAIDs, colchicine, corticosteroids or a combination thereof, and (b) in some patients, long-term prophylactic treatment with urate-lowering therapy (ULT) to prevent subsequent attacks.

**Desired Outcomes**

- Treatment goals for an acute attack are to: (a) achieve rapid and effective pain relief, (b) maintain joint function, (c) prevent disease complications, (d) avoid treatment-related adverse effects, (e) provide cost-effective therapy, and (f) improve quality of life.
- Infrequent gouty arthritis is a self-limited disease, and treatment usually focuses on symptomatic relief.

**Nonpharmacologic Therapy**

Nondrug modalities play an adjunctive role and usually are not effective when used alone. Immobilization of the affected extremity speeds resolution of the attack. Applying ice packs to the joint also decreases pain and swelling, but heat application may be detrimental.

**Pharmacologic Therapy**

**KEY CONCEPT** Nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine, and corticosteroids are considered first-line monotherapy options for acute attacks. Selection depends on number of joints affected, presence/absence of infection, clinician/patient preference, prior response, and patient factors such as comorbidities and renal function (Figure 59–2). Each drug class has a unique safety and efficacy profile in gout that should be considered carefully before choosing a specific agent (Table 59–1). Generally, the earlier in the course of the arthritic attack these agents are employed (ie, within 24 hours), the better the outcome. Corticotropin (adrenocorticotropic hormone, ACTH) and IL-1 inhibitors are alternatives in select cases. Opioid analgesics have little to no role in acute gout, which results from overwhelming inflammation.

**Nonsteroidal Anti-inflammatory Drugs**

NSAIDs have largely supplanted colchicine as the treatment of choice. These agents are most effective when given within the first 24 hours of the onset of pain. Most studies have shown similar results among agents, and no one NSAID is preferred over another as first-line treatment. Doses at the higher end of the therapeutic range are often needed. NSAIDs are usually continued at full doses until 24 hours after symptoms subside. Clinicians may consider tapering the dose if a patient has multiple comorbidities, including hepatic or renal failure.

Only naproxen, indomethacin, and sulindac are FDA approved for treatment of acute gout. Although indomethacin has been used traditionally, its relative cyclooxygenase-1 (COX-1) selectivity increases its gastropathy risk. Studies comparing indomethacin to other NSAIDs consistency show similar efficacy with higher side effects with indomethacin; thus, other generic NSAIDs may be preferred. The patient’s overall clinical status should be evaluated prior to NSAID initiation because adverse effects include gastropathy (primarily peptic ulcers), renal dysfunction, and fluid retention. NSAIDs generally should be avoided in patients at risk for peptic ulcers; those taking anticoagulants; and those with renal insufficiency, uncontrolled hypertension, or heart failure. Gastroprotective agents such as proton pump inhibitors may protect against ulcer development in patients receiving NSAIDs for acute gout.

Cyclooxygenase-2 (COX-2)–selective inhibitors (ie, celecoxib) produce results comparable with those of traditional NSAIDs. However, the need for large COX-2 inhibitor doses, cardiovascular safety concerns, and high cost make the risk-benefit ratio unclear for this disorder.

**Colchicine**

Colchicine has a long history of successful use and was the treatment of choice for many years. It is used less commonly today because of its low therapeutic index and more recently, increased cost. Colchicine is thought to exert its anti-inflammatory effects by interfering with the function of mitotic spindles in neutrophils by binding of tubulin dimers; this inhibits phagocytic activity. Colchicine is not considered to be an analgesic.

About two-thirds of patients with acute gout respond favorably if colchicine is given within the first 24 hours of symptom onset. Presently, colchicine is only indicated if given within 36 hours of attack onset. GI effects (eg, nausea, vomiting, diarrhea, and abdominal pain) are most common and are considered a forerunner of more serious systemic toxicity, including myopathy and bone marrow suppression (usually neutropenia). However, systemic toxicity can occur with oral colchicine without prior GI effects, especially in patients with renal insufficiency.

In the presence of severe renal impairment (creatinine clearance [CrCl] < 30 mL/min [0.5 mL/s]), dosing should be repeated no more than once every 2 weeks. Dose reductions are required when coadministered with p-glycoprotein or strong CYP3A4 inhibitors (eg, clarithromycin, verapamil, ritonavir, cyclosporine, ranolazine). Because of these problems, colchicine may be reserved for patients who are at risk for NSAID-induced gastropathy or who have failed NSAID therapy.
Acute Gout Attack
Assess pain intensitya and extent of joint involvement

Mild/moderate pain and/or limited joint involvement

Initiate monotherapy.\textsuperscript{b}
NSAID
Colchicine\textsuperscript{c}
Systemic corticosteroid

Severe polyarticular attack

Initiate combination therapy\textsuperscript{d} (see text)

Determine need for maintenance urate lowering therapy\textsuperscript{e}

Meets criteria

Initiate allopurinol or febuxostat first line\textsuperscript{f} (probenecid, alternate)

Monitor SUA every 2–5 weeks and gradually titrate agent as needed to achieve and maintain target < 6 mg/dL (357 µmol/L)\textsuperscript{g}

Inadequate criteria

Employ nonpharmacologic urate-lowering strategies and monitor for subsequent acute attacks

FIGURE 59–2. Treatment algorithm for hyperuricemia in gout. (NSAID, nonsteroidal anti-inflammatory drug; SUA, serum uric acid.)
\textsuperscript{a}Self-reported pain score using a visual analog scale of 6 or less is considered mild/moderate pain and 7 or more is considered severe pain.\textsuperscript{b}May consider switch to alternate monotherapy, add-on combination therapy, or off-label therapy for inadequate response (< 20% improvement in pain score within 24 hours or < 50% at 24 hours or longer).\textsuperscript{c}Colchicine recommended only if started within 36 hours of symptom onset.\textsuperscript{d}Intraarticular corticosteroids may be used in combination when only one or two large joints are affected.\textsuperscript{e}Criteria for ULT initiation include: Recurrent attacks (2 or more per year), evidence of tophus or tophi, chronic kidney disease stage 2 or worse, or past urolithiasis.\textsuperscript{f}Initiate concomitant anti-inflammatory prophylaxis and continue for indicated duration.\textsuperscript{g}May add on uricosuric therapy if unable to achieve target SUA on maximally dosed xanthine oxidase inhibitor therapy; switch to pegloticase for refractory cases.

Colcrys is the only single-ingredient oral colchicine product FDA approved for treatment of acute gout attacks. For many years prior to its release, generic colchicine products were available without FDA approval. In 2010, the FDA ordered manufacturers to discontinue marketing these unapproved generics. Colcrys is much more expensive than the generic compounds it replaced but has proper labeling and safety data. As part of the approval process, a dosing study showed that one dose initially and a single additional dose after 1 hour was just as effective as and less toxic than continued hourly colchicine dosing.\textsuperscript{30} Thus, the approved dosage regimen is 1.2 mg (two 0.6-mg tablets) at the onset of an acute flare, followed by 0.6 mg 1 hour later.\textsuperscript{31} The ACR guidelines suggest it can then be continued starting 12 hours later at a dose of 0.6 mg once or twice daily (prophylaxis dosing) until the gout attack is resolved.\textsuperscript{32} This is not part of the FDA-approved labeling but is an off-label recommendation based on pharmacokinetic data.\textsuperscript{30} Dose adjustment is required for renal insufficiency.

Colchicine should not be used for an acute attack if the patient is currently prescribed colchicine for prophylaxis and was previously treated with colchicine for an acute attack within the last 14 days. Intravenous colchicine (no longer commercially available) should never be used in gout management.\textsuperscript{6}

> Corticosteroids

It is important to determine the number of joints affected when considering a corticosteroid for first-line therapy. Systemic corticosteroids are a useful option in patients with contraindications to NSAIDs or colchicine (primarily renal impairment) or polyarticular attacks, especially in elderly patients. The ACR recommends initiating oral prednisone or prednisolone at a starting dose of at least 0.5 mg/kg daily for 5 to 10 days, followed by abrupt discontinuation, or full dose therapy for 2 to 5 days with a 7- to 10-day taper to discontinue.\textsuperscript{6} Oral methylprednisolone (ie, the 6-day dose pack consisting of a 21-tablet taper of 4 mg tablets, starting with 6 tablets on day 1 [divided into three separate doses] and ending with one tablet on day 6) and naproxen have been shown to be equivalent in treating acute gout attacks.\textsuperscript{32}
When only one or two large joints are affected, an intraarticular corticosteroid injection can provide rapid relief with a relatively low incidence of side effects, and it may be used in combination with either an NSAID, colchicine, or oral corticosteroid. Joint fluid obtained by arthrocentesis should be examined for evidence of joint space infection and crystal identification. If uric acid crystals are present and there is no infection, intraarticular injection can proceed.

Finally, an alternative regimen consisting of a single intramuscular injection of a long-acting corticosteroid such as triamcinolone acetonide, followed by oral prednisone or prednisolone may also be used. Adverse effects from corticosteroids include fluid retention, hyperglycemia, CNS stimulation, weight gain, GI upset, and increased risk of infection. Patients with diabetes should have blood glucose levels monitored carefully during the corticosteroid course, and caution should be exercised when treating patients with a history of peptic ulcer disease.

IM, intramuscular; NSAIDs, nonsteroidal anti-inflammatory drugs; po, by mouth; SC, subcutaneous.

<sup>a</sup>NSAIDs that are FDA approved for treatment of gout are indicated with an asterisk.

<sup>b</sup>Dose reduction recommended for renal impairment.

<sup>c</sup>Administration of IM triamcinolone should be followed by oral prednisone or prednisolone.

<sup>d</sup>Not FDA approved for this indication.

Drug regimens derived from various sources.

► **Interleukin-1 Inhibitors**

Several small clinical trials have demonstrated efficacy of IL-1 inhibitors in inhibiting inflammation associated with acute gout attacks. While their role is unclear and the available products (anakinra and canakinumab) are not FDA approved for this purpose, the ACR guidelines include off-label use as an option for severe acute attacks or for patients refractory to other agents.<sup>6</sup>

► **Combination Therapy**

In severe polyarticular attacks, particularly attacks involving multiple large joints, colchicine may be used in combination with an NSAID or oral corticosteroid. Intraarticular corticosteroid injections may be used in combination with any other first-line agent (NSAID, colchicine, oral corticosteroid).<sup>6</sup>

### Urate Lowering Therapy for Gout Prophylaxis

Gout is an episodic disease, and the number of attacks varies widely from patient to patient. Thus the benefit of long-term prophylaxis against acute gout flares must be weighed against the cost and potential toxicity of therapy that may not be necessary in all patients. **KEY CONCEPT** Asymptomatic hyperuricemia generally does not require treatment.

### Nonpharmacologic Therapy

Historically, lifestyle modifications alone have been insufficient for lowering SUA levels in gout patients. Patients should be...
ed educated to engage in regular exercise to lose weight if obese, strictly limit or discontinue ethanol consumption, maintain hydration, and manage other comorbidities (eg, hypertension, diabetes). Low-purine diets, including avoiding organ meats, and limiting sardines, shellfish, beef, pork, and lamb are not well tolerated; instead, dietary recommendations should focus on general nutrition principles. Some studies have shown that low-fat dairy products, coffee, and vitamin C may confer a protective effect. Complementary therapies that are considered to be inappropriate for gout due to insufficient evidence of benefit include cherry juice/extract, willow bark extract, ginger, flaxseed, charcoal, strawberries, black current, burdock, sour cream, olive oil, horsetail, pears, and celery root.4,3 Drugs that may cause or aggravate hyperuricemia should be discontinued if clinically appropriate. Few patients adhere to lifestyle modifications long term, and pharmacologic therapy usually is needed to treat hyperuricemia adequately.33

**Pharmacologic Therapy**

**Patients with recurrent attacks (2 or more per year), evidence of tophus or tophi, CKD stage 2 or worse, or past arthritis are candidates for prophylactic therapy with allopurinol, febuxostat, probenecid, or pegloticase to lower SUA levels (see Figure 59–2).** Because hyperuricemia is the strongest modifiable risk factor for acute gout, prophylactic therapy commonly involves either decreasing uric acid production or increasing its excretion (Table 59–2). The goal of therapy is to decrease SUA levels significantly, leaving less uric acid available for conversion to MSU crystals.4

Ideally, the selection of long-term prophylactic therapy involves determining the cause of hyperuricemia (primarily by analyzing a 24-hour urine collection for uric acid) and tailoring therapy appropriately. If less than 600 mg (3.6 mmol) of uric acid is found in the 24-hour sample, the patient is considered an overproducer. If more than 600 mg (3.6 mmol) of uric acid is found, the patient is considered an underexcretor. However, this approach is not used commonly for several reasons. The urine collection is inconvenient for patients and clinicians and does not identify patients who may be both overproducers and underexcretors of uric acid. Also, drugs used to increase uric acid excretion (uricosuric agents) generally are not as well tolerated as drugs that decrease production, and uricosurics increase the risk of uric acid nephrolithiasis.34

Because allopurinol (which reduces uric acid production) is effective in both overproducers and underexcretors and is generally well tolerated, many clinicians forego the 24-hour urine collection and treat patients empirically with it. Both allopurinol and febuxostat are xanthine oxidase inhibitors (XOIs) and are considered to be first-line Ult agents. Probenecid, a uricosuric agent, is an alternative first-line option, whereas pegloticase is generally reserved for refractory cases.5

po, by mouth; SUA, serum uric acid.

4Initiation dose reduction recommended for renal impairment.

Drug regimens derived from various sources.

**Key Concept** Patients with recurrent attacks (2 or more per year), evidence of tophus or tophi, CKD stage 2 or worse, or past arthritis are candidates for prophylactic therapy with allopurinol, febuxostat, probenecid, or pegloticase to lower SUA levels.

**Key Concept** ULT should be continued in patients even during acute flares.

**Allopurinol**

Most patients in the US are treated with allopurinol, which usually is effective if the dosage is titrated appropriately. The drug and its primary active metabolite, oxypurinol, reduce SUA concentrations by inhibiting the enzyme xanthine oxidase, thereby blocking the two-phase oxidation of hypoxanthine and xanthine to uric acid.4

Allopurinol is well absorbed, with a short half-life of 2 to 3 hours. The half-life of oxypurinol approaches 24 hours, allowing allopurinol to be dosed once daily. Oxypurinol is cleared primarily by renal mechanisms and can accumulate in patients with reduced kidney function.

Allopurinol may be started during an acute gout attack only if anti-inflammatory treatment is also initiated, because sudden shifts in SUA levels from mobilization of tissue urate stores may precipitate or exacerbate gouty arthritis. Rapid shifts in SUA can change the concentration of MSU crystals in synovial fluid, causing more crystals to precipitate. Thus most clinicians provide anti-inflammatory prophylaxis during initiation of Ult with colchicine (0.6 mg once or twice daily or 0.3 mg daily if severe renal impairment) or a low-dose NSAID (eg, naproxen 250 mg twice daily) with acid-suppressing therapy (eg, omeprazole 20 mg once daily). If a patient is being treated with colchicine for an acute attack, the prophylactic colchicine dose may be administered 12 hours after the last treatment dose. This approach, with colchicine having a stronger evidence grade, is supported by the ACR guidelines. Guidelines recommend that all acute gout patients receive prophylaxis when Ult is started with continuation of therapy for at least 6 months or up to 3 to 6 months after no clinical evidence of gouty activity is apparent and the target SUA has been achieved.6 Patients receiving colchicine for prophylaxis should be screened for drug–drug interactions (via the cytochrome p-450 system) that may increase the risk of colchicine adverse effects. Low-dose prednisone or prednisolone (less than 10 mg/day) is an alternative for patients unable to take colchicine or NSAIDs.

The initial dose of allopurinol is based on the patient’s renal function. If renal function is normal, an initial dose no greater than 100 mg daily is recommended. The initial dose should be reduced to 50 mg daily in patients with a CrCl less than 30 mL/min (0.5 mL/s).1 The relationship between allopurinol dose and its most severe side effects, including allopurinol hypersensitivity syndrome (AHS), is controversial.35,36 However, the dose can be adjusted upward every 2 to 5 weeks as needed and tolerated, even in patients with renal insufficiency provided that they are monitored and educated appropriately.5,37 Historically, allopurinol was dosed according to renal function with stringent
maximizing dosages. The 2012 ACR guidelines recommend titrating the dose to goal SUA regardless of renal function.

- SUA levels must be monitored every 2 to 5 weeks during titration, then every 6 months after the target SUA is achieved. The target SUA level is less than 6 mg/dL (357 μmol/L) in all cases and perhaps even less than 5 mg/dL (297 μmol/L) in more severe disease involving tophi. The allopurinol dose should be titrated upward (to a maximum of 800 mg/day) or downward as these levels dictate. The typical dose prescribed is 300 mg/day in patients with normal renal function, but this dose often fails to achieve the target SUA level.5

- Allopurinol is typically well tolerated; nausea and diarrhea occur uncommonly. A generalized, maculopapular rash occurs in about 2% of patients.38 Although usually mild, this can progress to severe skin reactions such as Stevens-Johnson syndrome. The most serious side effect is AHS, which may involve severe desquamating skin lesions, high fever (usually greater than 39.0°C [102.2°F]), hepatic dysfunction, leukocytosis with predominant eosinophilia, and renal failure. The risk appears to be highest in the first few months of therapy, and although rare, this severe reaction has a 20% to 25% mortality rate.3,39,40 Prior to initiating allopurinol, pharmacogenetic screening via human leukocyte antigen (HLA)-B*5801 testing is recommended for patients at an elevated risk for AHS (eg, Koreans with stage 3 or worse CKD and all individuals of Han Chinese and Thai descent). If results are positive, the patient should be provided with an alternative to allopurinol. Patients with a history of AHS should never again receive allopurinol (including desensitization) or oxypurinol (which is available outside the United States). Patients with a mild skin rash who require allopurinol can be desensitized to it using published protocols or be switched to febuxostat.41,42

There are several important drug–drug interactions with allopurinol. The effects of both theophylline and warfarin may be potentiated by allopurinol. Azathioprine and 6-mercaptopurine are purines whose metabolism is inhibited by concomitant allopurinol therapy; the dose of these drugs must be reduced by 75% with allopurinol cotherapy. Patients taking allopurinol who receive ampicillin are at increased risk of skin rashes.

> Febuxostat

Febuxostat is a nonpurine XO inhibitor structurally distinct from allopurinol that is FDA approved for chronic hyperuricemia associated with gout. The initial dose is 40 mg orally once daily. The dose may be increased to 80 mg orally once daily if the SUA does not decrease to 6 mg/dL (357 μmol/L) or less after 2 weeks of treatment. No dosage adjustment is necessary in patients with mild or moderate renal impairment (CrCl 30–89 mL/min [0.5–1.48 mL/s]); however, febuxostat is not recommended in patients with severe renal insufficiency (CrCl < 30 mL/min [0.5 mL/s]).34 Because of its potency and rapid reduction of SUA levels, anti-inflammatory prophylaxis with low-dose colchicine or an NSAID is also recommended during initiation and titration of therapy and for at least 6 months as previously discussed for allopurinol.

- Adverse effects of febuxostat include nausea, arthralgias, rash, and transient elevation of hepatic transaminases. Periodic liver function tests are recommended (eg, at baseline, 2 and 4 months after starting therapy, and then periodically thereafter). Due to differences in chemical structure, febuxostat would not be expected to cross-react in patients with a history of allopurinol hypersensitivity syndrome.

Due to cost concerns, febuxostat should generally be reserved for patients who do not tolerate allopurinol and those who

Patient Encounter, Part 2

**PMH:** Obesity—120 kg (264 lb) and 5’5” (165 cm) tall, hypertension, dyslipidemia, allergic rhinitis

**FH:** Father unknown. Mother has coronary artery disease and hypertension. No siblings

**SH:** He is currently unemployed but previously drove trucks for a local delivery company until losing his job 2 weeks ago. He drinks soda during the day and three to four beers most nights of the week. He denies use of tobacco products or illicit drugs. He admits to a poor diet consisting of many processed and fast foods and likes to snack on candy

**Allergies:** NKDA

**Meds:** Hydrochlorothiazide 25 mg once daily (adherent), amlodipine 10 mg once daily (adherent), rosuvastatin 20 mg at bedtime (nonadherent), cimetidine 300 mg at bedtime as needed (self-prescribed), loratadine 10 mg once daily (during allergy season), aspirin 325 mg twice daily as needed (self-prescribed for headaches), colchicine 1.2 mg (two 0.6-mg tablets) for one dose, followed by 0.6 mg 1 hour later and 0.6 mg once daily thereafter until gout attack resolves (completed 10-day course 2 months ago for acute gouty attack)

**ROS:** (–) Fatigue, (–) N/V/D, HA, SOB, chest pain, cough

**PE:**

**VS:** 139/92, P 72, RR 18, T 36.1°C (96.9°F)

**Skin:** Warm, dry with excessive warmth surrounding left great toe

**HEENT:** NC/AT, PERLRA, TM’s intact

**CV:** RRR, normal S1 and S2, no m/r/g

**Chest:** CTA

**Abd:** Soft, NT/ND

**Ext:** No c/c, trace edema in both ankles

**Neuro:** A&O x 3, CN II to XII intact

**Labs:** Serum creatinine 0.9 mg/dL (80 μmol/L), SUA 8.1 mg/dL (482 μmol/L), WBC + diff WNL

**Other:** 24-hour urine collection, joint aspirate, and x-ray not performed

**What risk factors promote gout and hyperuricemia in this patient?**

**Given this additional information, what is your assessment of the patient’s condition?**

**Identify your gout treatment goals for this patient.**

**What nonpharmacologic and pharmacologic alternatives are available for this patient’s acute gouty attack?**

**What alternatives are available for urate-lowering therapy for gout prophylaxis in this patient?**
Patient Encounter, Part 3

Based on the information available, create a care plan for this patient’s gout. The plan should include: (a) a statement of the drug-related needs and/or problems, (b) a patient-specific detailed therapeutic plan, and (c) monitoring parameters to assess efficacy and safety.

cannot achieve SUA levels of 6 mg/dL (357 μmol/L) or less despite maximal allopurinol therapy.¹

**Probenecid**

Probenecid is a uricosuric agent that blocks the tubular reabsorption of uric acid, increasing its excretion. Because of its mechanism of action, probenecid is not recommended for urate overproducers and is contraindicated in patients with a history of urolithiasis or urate nephropathy. Probenecid loses its effectiveness as renal function declines and should be avoided when the CrCl is 50 mL/min (0.83 mL/s) or less.⁴ Probenecid is considered an alternate first-line agent if XOI therapy is either not tolerated or contraindicated. It may also be added to XOI therapy that has been titrated to the maximum dose without attainment of the target SUA level.⁶

Although generally well tolerated, probenecid can cause GI side effects such as nausea as well as fever, rash, and rarely, hepatic toxicity. Patients should be instructed to maintain adequate fluid intake and urine output to decrease the risk of uric acid stone formation. Some experts advocate alkalinizing the urine to decrease this risk, but no specific recommendations are provided.

**Other Uricosuric Agents**

Other medications with mild uricosuric effects may be appropriate adjunctive therapy in some patients. Losartan increases both uric acid excretion and urine pH and may be an option in hypertensive patients with gout. Fenofibrate is also uricosuric and may be appropriate in select dyslipidemic patients with gout.⁴⁶ Either one of these agents may be combined with a XOI in patients who fail to achieve the target SUA level on maximized therapy.⁵

**Pegloticase**

Gout does not occur in most nonprimate mammals because these species produce the enzyme uricase, which catalyzes oxidation of uric acid into the more soluble compound allantoin, which is readily excreted. Humans lack this enzyme, which allows uric acid to accumulate, leading to gout in some individuals.

Pegloticase is a recombinant form of uricase (also known as urate oxidase) conjugated to polyethylene glycol. It is FDA approved for treatment of chronic gout refractory to other therapies. The approved dose of 8 mg by IV infusion over at least 2 hours every 2 weeks rapidly (within 6 hours) decreased SUA in subjects in published trials.⁴⁷ However, pegloticase should be

Patient Care Process

**Patient Assessment:**
- Assess patient symptoms to determine time of attack onset, joint(s) affected, pain level, and observe physical signs (joint warmth, swelling, and redness).
- Review patient history for contributing lifestyle factors (ie, alcohol use) and comorbidities including CKD that may exacerbate hyperuricemia or help to guide therapy.
- Obtain thorough medication history for prescription and nonprescription drug and dietary supplement use. Determine whether any products such as diuretic therapy may be contributing to hyperuricemia.
- Consider evaluating the SUA level to confirm presence of hyperuricemia.
- If a gout diagnosis has not been confirmed previously, consider aspiration of the affected joint or tophus to identify uric acid crystals.

**Therapy Evaluation:**
- Discontinue nonessential urate-elevating medications.
- If a patient is currently receiving pharmacotherapy, assess efficacy (ie, frequency and severity of attacks), safety/adverse reactions, adherence, and potential drug interactions.
- Ensure the patient has met criteria for ULT if already prescribed.
- Determine if the patient has prescription insurance and whether recommended agents (eg, colchicine) are included on the formulary.

**Care Plan Development:** (see Figure 59–2)
- Initiate therapy to treat acute gout attack within 24 hours (see Table 59–1).
- Select therapy based on comorbidities and potential for adverse effects.
- Assess need for continuous ULT (see Table 59–2). Use patient factors such as comorbidities to select an agent.
- Most patients need adjunctive therapy with low-dose colchicine or an NSAID during initiation or titration of ULT to prevent a rebound flare.
- Initiate ULT during an acute attack only in conjunction with effective anti-inflammatory therapy.
- Educate the patient on hyperuricemia/gout, drug therapy, and appropriate lifestyle modifications that may improve symptoms (eg, weight loss, avoidance of ethanol).

**Follow-up Evaluation:**
- Titrate ULT to achieve the target SUA; monitor the SUA concentration during ULT titration and periodically thereafter.
- Evaluate presence of adverse drug reactions, allergies, and interactions.
- Reinforce adherence with the regimen to prevent future gout attacks and long-term complications.
limited to patients with severe gout with tophi or nephropathy that has not responded to other agents because of significant adverse effects, including gout flares, infusion reactions, anaphylaxis (in up to 5% of patients) that mandates pretreatment with antihistamines and corticosteroids, the inconvenience of IV therapy, and its high cost. Pegloticase is contraindicated in patients with G6PD deficiency due to the risk of hemolysis and methemoglobinemia; therefore, patients should be screened prior to initiation of therapy.

**OUTCOME EVALUATION**

**Acute Gout**

- Monitor the patient for pain relief and decreased swelling of the affected joint(s). Both parameters improve significantly within 48 hours of starting therapy.
- Assess the patient’s complaints and objective information for adverse effects. For NSAID therapy, be alert for new-onset epigastric pain, dark or tarry stools, blood in vomitus, dizziness or lightheadedness, development of edema, decreased urine output, or shortness of breath. For colchicine, monitor for nausea or vomiting, diarrhea, easy bruising, cold or flu-like symptoms, lightheadedness, muscle weakness, or pain. Advise the patient to inform you of any new medications started or stopped while taking colchicine.
- Monitor patients receiving intraarticular corticosteroid injections for increased swelling or pain at the injection site.
- Assess patients receiving systemic corticosteroids for mental status changes, fluid retention, increased blood glucose, muscle weakness, or development of new infections.

**Urate Lowering Therapy**

- Monitor the SUA level every 2 to 5 weeks during ULT initiation and titration. Adjust the dose of ULT to achieve a target SUA level of less than 6 mg/dL (357 μmol/L) or optionally less than 5 mg/dL (297 μmol/L) in more severe disease. Then continue measurements every 6 months thereafter.
- Concomitantly initiate anti-inflammatory prophylaxis and continue for the greater of 6 months or 3 to 6 months after achieving target SUA level with no gout signs/symptoms.
- Assess for new gouty arthritis attacks or development of tophi.
- Evaluate patients taking allopurinol for development of rash, nausea, or new fever. These symptoms usually appear within the first 3 months of therapy but can occur anytime.
- Evaluate patients prescribed febuxostat for presence of nausea, arthralgias, rash, and transient elevation of hepatic transaminases.
- Assess patients receiving probenecid for fever, nausea, or skin rash. Reevaluate therapy if a significant decrease in urine output occurs.
- If pegloticase is used, monitor SUA levels before each 2-week IV infusion.
- Evaluate patients on pegloticase for development of gouty flares and infusion reactions, which may include anaphylaxis. The manufacturer recommends giving an antihistamine and perhaps low-dose methylprednisolone before the infusion to minimize reactions.

** Abbreviations Introduced in This Chapter**

- ACR American College of Rheumatology
- ACTH Adrenocorticotropic hormone
- AHS Allopurinol hypersensitivity syndrome
- COX Cyclooxygenase
- G6PD Glucose-6-phosphate dehydrogenase

**REFERENCES**

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiologic principles of tissue injury and inflammation.
2. Identify the desired therapeutic outcomes for a patient with musculoskeletal injury or pain.
3. Identify the factors that guide selection of an analgesic or counterirritant for a particular patient.
4. Recommend appropriate nonpharmacologic and pharmacologic therapy for a patient with musculoskeletal injury or pain.
5. Design a patient education plan, including nonpharmacologic therapy and preventative strategies.

INTRODUCTION

The musculoskeletal system consists of muscles, bones, joints, tendons, and ligaments. Disorders related to the musculoskeletal system often are classified by etiology. Acute soft-tissue injuries include strains and sprains of muscles and ligaments. Repeated movements in sports, exercise, work, or activities of daily living can lead to repetitive strain injury, where cumulative damage occurs to the muscles, ligaments, or tendons. Although tendonitis and bursitis can arise from acute injury, more commonly these conditions occur as a result of chronic stress. Other forms of chronic musculoskeletal pain, such as pain from rheumatoid arthritis (see Chapter 57) or osteoarthritis (see Chapter 58), are discussed elsewhere in this textbook.

EPIDEMIOLOGY AND ETIOLOGY

Musculoskeletal disorders are commonly self-treated, so true estimates of the incidence of both acute and chronic injury are difficult to obtain. In the United States, over 60 million musculoskeletal injuries occur each year, with 60% of episodes treated in ambulatory care offices. These disorders account for a large portion of medical care expenditures and are a leading cause of work absenteeism and disability, resulting in a substantial economic burden from lost productivity and lost wages.

Some musculoskeletal disorders are induced by trauma at the workplace either via a one-time overexertion or through repetition and cumulative trauma. Strains and sprains are the most common workplace injuries, representing over three-fourths of all musculoskeletal injuries. Musculoskeletal injuries are more likely to occur with heavy lifting, exposure to vibration, or working overhead.

In the elderly, musculoskeletal injuries may not be related to work but to daily life. Half of all musculoskeletal injuries occur in the home with falls being the most common cause for those aged 65 and older. In children and adolescents, fractures are more common than muscle and tendon injuries because growth spurts cause bones to weaken while the muscle–tendon unit tightens. Muscle injuries comprise the majority of sports-related injuries, and roughly half are related to overuse. The ankle is the most common site of sports injury. Basketball, which requires rapid acceleration and higher speeds, poses the greatest risk of muscle sprain. Other sports requiring pivoting at higher speeds, such as volleyball and soccer, also pose a high risk of overuse and acute injury, especially to the knee.

Overuse musculoskeletal injury is the phrase used to describe disorders arising from repetitive motion. This injury is common in activities such as running, particularly during periods of increased intensity or duration of training. It also can occur in the workplace with repeated, unvaried motion.

PATHOPHYSIOLOGY

Skeletal muscle consists of muscle fibers linked together by connective tissue. Tendons and ligaments are composed of collagenous fibers that have a restricted capability to stretch. Tendons connect muscle to bone, whereas ligaments connect bone to bone.

Muscle Strains and Sprains

A sprain is an overstretching of supporting ligaments that results in a partial or complete tear of the ligament. Although a strain also arises from an overstretching of the muscle–tendon unit, it is marked by damage to the muscle fibers or tendon without tearing of the ligament. The key difference is that a sprain involves damage to ligaments, whereas a strain involves damage primarily to muscle.

Overloading the muscle and connective tissue results in complete or partial tears of the skeletal muscle, tendons, or ligaments. This usually occurs when the muscle is activated in an eccentric contraction, defined as a contraction in which...
The process also facilitates production of additional PGs. In a damaged tissue causes tenderness, soreness, and heat, and mechanical stimuli. Excitable, and the nerve fibers are more reactive to serotonin, pain sensitization. These substances make nerve endings more inflammatory mediators lower the pain threshold through peripheral as bradykinin. Bradykinin, PGs, leukotrienes, and other inflammatory cells remove damaged tissue.

Next, arachidonic acid is transformed by cyclooxygenase (COX) limits range of motion. Phagocytic cells release cytokines, including interleukins, interferon, and tumor necrosis factor. In addition to increasing vascular permeability, PGs also induce pain by sensitizing pain receptors to other substances such as bradykinin. Bradykinin, PGs, leukotrienes, and other inflammatory mediators lower the pain threshold through peripheral pain sensitization. These substances make nerve endings more excitable, and the nerve fibers are more reactive to serotonin, heat, and mechanical stimuli. The increased sensitization in the damaged tissue causes tenderness, soreness, and hyperalgesia. The process also facilitates production of additional PGs. In a cyclic fashion, the PGs then sensitize the nerves to bradykinin action.

Without interruption, the neurochemicals ultimately lead to a firing of the unmyelinated or thinly myelinated afferent neurons. This sends messages along the pain pathway in the periphery and communicates the pain message to the CNS. Interruption of this cycle may occur via the effects of anti-inflammatory agents such as aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs). Nerve receptors, or nociceptors, release substance P and other peptides when they are activated. Substance P mediates the production and release of inflammatory mediators and acts as a potent vasodilator. This receptor activation also increases the sensitivity of nociceptors to painful stimuli. Capsaicin relieves pain by stimulating the release of substance P from sensory nerve fibers, ultimately depleting stores of substance P.

**CLINICAL PRESENTATION AND DIAGNOSIS**
See next page for information on the clinical presentation and diagnosis of musculoskeletal disorders.

**TREATMENT**

**Desired Outcomes**

**KEY CONCEPT** The two primary goals of treating musculoskeletal disorders are to: (a) relieve pain and (b) maintain functionality. This is accomplished by decreasing the severity and duration of pain, shortening the recovery period, and preventing acute injury pain from becoming chronic pain. If these goals are achieved, functional limitations are decreased. Ideally, a patient should be able to continue to perform activities of daily living and maintain normal functions in the workplace. Children ideally should be able to maintain usual play activities and sports schedules.

Further goals include a return to usual activity and prevention of future injury. It is also important to minimize the potential for adverse drug events during treatment.

**General Approach to Treatment**

Treatment of musculoskeletal disorders involves three phases: (a) therapy of an acute injury using the rest, ice, compression, and elevation (RICE) principle; (b) pain relief using oral or topical agents; and (c) lifestyle and behavioral modifications for rehabilitation and to prevent recurrent injury or chronic pain (Figure 60–1).

In many cases, musculoskeletal disorders are self-treated with over-the-counter (OTC) oral or topical agents. However, further evaluation may be warranted if acute pain persists longer than

---

**Patient Encounter 1, Part 1**

A 28-year-old woman presents with left ankle pain. She stepped on one of her son’s toys earlier today after coming down the stairs at home and twisted her ankle. The pain occurs at rest and is worsened with weight bearing on the ankle and with rotation or movement. There is moderate swelling and bruising of the left ankle.

What information is suggestive of a musculoskeletal disorder?

What is your assessment of the patient’s ankle pain?

What additional information do you need to formulate a treatment plan?
**Clinical Presentation and Diagnosis of Musculoskeletal Disorders**

### General
- Clinical presentation varies based on etiology of the disorder.
- Repetitive strain or overuse injuries may have a gradual onset.
- Disorders due to acute injury may be associated with other signs of injury such as abrasion.
- Low back pain is often chronic.

### Signs and Symptoms of Acute Soft-Tissue Injury (Strains, Sprains)
- Discomfort ranging from tenderness to pain may occur at rest or with motion
- Swelling and inflammation of the affected area
- Bruising
- Loss of motion
- Mechanical instability

### Signs and Symptoms of Repetitive Strain or Overuse Injury (Tendonitis, Bursitis)
- Pain and stiffness that occurs either at rest or with motion
- Localized tenderness on palpation

### Other Diagnostic Tests and Assessments
- **Radiograph (x-ray)**: Evaluate bony structures to rule out fracture, malalignment, or joint erosion as the primary cause of pain.
- **MRI**: Soft-tissue imaging to evaluate for tendon or ligament tears.
- **Ultrasound**: Superficial soft-tissue imaging to evaluate for tears in tendons or ligaments. Ultrasound does not penetrate bone, so it is of limited usefulness for assessing tendons or ligaments deep within joints.
- **Pain scale**: Patient self-rating on a scale of zero (no pain) to 10 (worst possible pain). Used to assess pain both at rest and with movement. Determined at baseline and to assess response to therapy.

### Nonpharmacologic Therapy: RICE

**I. Nonpharmacologic**

**II. Pharmacologic options**

- **Nonsteroidal anti-inflammatory drugs (NSAIDs)**
- **Acetaminophen**
- **Salicylates**

**III. Nonpharmacologic**

- **Rehabilitation**
- **Prevention of recurrence**

---

In children and adolescents, treatment practices are similar to the approach in adults with a focus on nonpharmacologic therapy and oral analgesics. Children younger than 2 years, elderly persons, and pregnant women also may need special care. Elderly patients may be more prone to systemic effects because of thinning of the skin and increased absorption of topical agents and drug interactions from polypharmacy.

---

**FIGURE 60–1.** Treatment plan for musculoskeletal injury or disorder.
**General Guidelines**

- **Therapeutic Benefit**
  - Compress the affected area with an elastic bandage or support

**Anti-inflammatory**
- Rest the affected area
- Cool the affected area by submersion in cool water (13°C [55°F]) or by application of crushed ice in a plastic bag covered with a thin cloth
- Elevate the area (especially the extremities) above heart level

**Pharmacologic Therapy**

- **Oral Analgesics**
  - Nonopioid analgesics, including acetaminophen, aspirin, and NSAIDs, are used commonly for musculoskeletal disorders. These agents all provide analgesia, but aspirin and NSAIDs also work peripherally by inhibiting the enzyme COX to decrease production of PGE,
    the principal mediator of acute inflammation. Although the mechanism of action of acetaminophen is less clear, it appears that acetaminophen acts as a weak inhibitor of PG production via COX-2 inhibition and exerts only a mild anti-inflammatory effect.

- **Acetaminophen**
  - Acetaminophen is the drug of choice for mild-to-moderate regional musculoskeletal pain without inflammation. Comparative trials between acetaminophen and oral NSAIDs demonstrate equivalent analgesia in some situations, but NSAIDs may be preferred in others. Therefore, if adequate analgesia is not achieved with acetaminophen, switching to an NSAID is a reasonable alternative. Acetaminophen offers the advantage of less GI toxicity than NSAIDs. Although tolerability of acetaminophen is high at therapeutic doses, hepatotoxicity has been reported after overdose and at therapeutic doses, especially in combination with other factors. Patients should not exceed 4 g/day of acetaminophen to minimize the risk of liver injury. Acetaminophen should be used with caution in patients who have liver disease or consume alcohol because of the risk of hepatotoxicity. Due to concern over liver injury, many nonprescription products are now labeled with a maximum recommended dose of 3 g/day. In addition, oral prescription combination products are limited by the U.S. Food and Drug Administration (FDA) to 325 mg acetaminophen per dosage unit.

- **Salicylates**
  - Aspirin is not more effective than acetaminophen, and it is not recommended for treatment of acute musculoskeletal pain because its adverse effects may be more common and severe. Gastric irritation is more common with aspirin, and bleeding risk is increased because aspirin irreversibly inhibits platelet aggregation. Patients with aspirin-induced asthma should avoid aspirin and other salicylates. Due to the risk of Reye syndrome, aspirin should be avoided in persons younger than age 19 during episodes of fever-causing illnesses.

Some salicylates are specifically marketed for musculoskeletal back pain, such as magnesium salicylate. However, no studies specifically support use of these salicylates over other systemic analgesics. Magnesium salicylate should be used with caution in patients with renal impairment due to risk of hypermagnesemia.

**NSAIDs**
- Oral NSAIDs are used commonly for musculoskeletal pain because of their availability without a prescription and anti-inflammatory effects. NSAIDs are a preferred choice over acetaminophen in musculoskeletal disorders in which...
inflammation is the primary problem.\textsuperscript{4,15,23} As a result, NSAIDs are particularly beneficial for chronic overuse injury, in which inflammation is central to the pain and loss of motion. Although NSAIDs may be helpful in relieving pain and inflammation in tendinitis, many tendinopathies are not associated with inflammation. Therefore, use of a simple analgesic such as acetaminophen may relieve pain adequately.\textsuperscript{2}

The analgesic effects of NSAIDs are attributed to inhibition of the COX-2 enzyme, whereas the negative GI effects are due to inhibition of COX-1.\textsuperscript{15} Patients taking oral anticoagulants, those with a history of peptic ulcer disease, or others at high risk for GI complications may be considered candidates for a COX-2 inhibitor (eg, celecoxib) or a combination of a nonselective NSAID with a gastroprotective agent such as a proton pump inhibitor (see Chapter 58). Combination of any NSAID, including COX-2 inhibitors, with alcohol can increase GI adverse effects. Additionally, all NSAIDs should be used with caution in patients with aspirin-induced asthma.\textsuperscript{15}

Both nonselective NSAIDs and COX-2 inhibitors are associated with nephrotoxicity.\textsuperscript{23} Furthermore, NSAIDs, including selective COX-2 inhibitors, may increase the risk of myocardial infarction. However, this risk may be higher for the COX-2 inhibitors due to an imbalance in thromboxane A\textsubscript{2} relative to prostacyclin levels creating a prothrombotic environment. A more detailed discussion of the relative risks of nonselective NSAIDs and COX-2 inhibitors and treatment options based on the cardiovascular and GI risk of the individual patient appears elsewhere in this text (see Chapter 58).

\textbf{Opioids} Opioid analgesics can be used for patients not responding adequately to nonopioid analgesics or for moderate-to-severe pain.\textsuperscript{4} These agents generally are given alone or in combination with simple analgesics such as acetaminophen. Tolerance and physical dependence are considerations but less of a concern when treating acute pain. When used in equivalent doses, opioids produce similar pain relief and adverse effects such as sedation, nausea, constipation, and respiratory depression (see Chapter 34).

\textbf{Topical (External) Analgesics}
Topically (or externally) applied drugs that exert a local analgesic, anesthetic, or antipruritic effect by either suppressing cutaneous sensory receptors or by stimulating these receptors in a counterirritant fashion are termed \textit{external analgesics}.\textsuperscript{18} These medications are applied directly to the affected area to create high local concentrations of the drug.\textsuperscript{15,24} Formulations include gel, cream, lotion, patch, liquid, liniment, or aerosol spray. Negligible systemic concentrations are achieved with intact skin, minimizing systemic adverse effects. Topical application should not be confused with transdermal delivery, in which drug absorption into the bloodstream produces a systemic effect. Musculoskeletal disorders often are treated with topical (but not transdermal) medications.

After application, the topical medication penetrates the skin to the soft tissue and peripheral nerves.\textsuperscript{18} At the site, topical analgesics suppress the sensitization of pain receptors, thereby reducing pain and burning. Examples include topical NSAIDs and local anesthetics such as lidocaine. In contrast, \textit{counterirritant} products are external analgesics that stimulate cutaneous sensory receptors, producing a burning, warming, or cooling sensation that masks the underlying pain. In effect, the irritation or inflammation caused by the counterirritant distracts from the underlying pain. Menthol and capsaicin are examples of counterirritants.

Some patients prefer external analgesics to systemic analgesics because the rubbing during application can be comforting.\textsuperscript{25} External analgesics are useful adjuvants to nonpharmacologic therapy and systemic analgesic therapy to provide additional relief. These agents are also an option in patients who cannot tolerate systemic analgesics. Because these products are not in pill form and many are available without a prescription, they may be overused or misused. This prompted the FDA to caution consumers that the agents are medicines that may also cause harm.\textsuperscript{26} Clinicians should advise patients to read and follow directions on the labels of OTC products.

\textbf{Topical NSAIDs}. In acute soft-tissue injury such as strains and sprains, topical NSAIDs have efficacy that is superior to that of placebo and similar to that of oral NSAIDs.\textsuperscript{24,27} Tissue concentrations of topical NSAIDs are high enough to produce anti-inflammatory effects, but systemic concentrations after application remain low.

Diclofenac is the only topical NSAID commercially available in the United States.\textsuperscript{27–31} Diclofenac patch (Flector Patch) is indicated specifically for topical treatment of acute pain from minor sprains and strains.\textsuperscript{28} The patch is applied to the most painful area twice daily. Diclofenac gel (Voltaren Gel) is indicated for joint pain in the knees and hands secondary to osteoarthritis; it is applied up to four times daily.\textsuperscript{29} Diclofenac solution (Pennsaid) is indicated for osteoarthritis of the knee; it is applied to the knee and is available in a solution applied via dropper four times daily or via measured pump two times daily.\textsuperscript{27–31} Patient education for topical NSAIDs is outlined in Table 60–2.\textsuperscript{27–29,31}

Data from Refs. 27–29 and 31.
Theoretically, the risk of serious GI adverse events should be less than with oral NSAIDs, but long-term studies evaluating these events are lacking. Like oral NSAIDs, topical NSAIDs should be used with caution in patients with a history of GI bleeding or ulcer.

Local cutaneous adverse reactions (eg, erythema, rash, pruritus, and irritation) are reported and may be due in part to the vehicle used. Theoretically, the risk of serious GI adverse events should be less than with oral NSAIDs, but long-term studies evaluating these events are lacking. Like oral NSAIDs, topical NSAIDs should be used with caution in patients with a history of GI bleeding or ulcer.

Local Anesthetics. Nonprescription topical anesthetics such as lidocaine and benzocaine are available in many types of products. Local anesthetics decrease discharges in superficial somatic nerves and cause numbness on the skin surface but do not penetrate deeper structures such as muscle where the pain often lies.

However, local anesthetics are helpful when abrasion accompanies the injury. Application of an OTC antibiotic ointment containing an anesthetic provides soothing relief, promotes healing of abrasions, and prevents soft-tissue infection. Minor abrasions should be cleansed with mild soap and water before application. More severe abrasions may require removal of debris by a clinician followed by irrigation with normal saline.

Counterirritants. Counterirritants are categorized by the FDA into four groups (groups A through D) based on their primary actions (Table 60–3). They produce a feeling of warmth, cooling, or irritation that diverts sensation from the primary source of pain. Because these irritant effects are central to the beneficial actions, counterirritants should not be combined with topical anesthetics or topical analgesics.

Counterirritants are indicated for the temporary relief of minor aches and pains related to muscles and joints. These symptoms may be associated with simple backache, arthritis, strains, sprains, or bruises. Many are available as combination products with ingredients from different counterirritant groups. Active ingredients in marketed products sometimes change; clinicians should be aware of the current ingredients before providing a product recommendation.

Patient education on proper use of counterirritants is essential to therapeutic success (Table 60–4).

Rubefacients (group A) are counterirritants that produce redness on application. Topical rubefacients containing salicylates (eg, methyl salicylate) are used most commonly. Turpentine oil is no longer judged as either safe or effective but remains in a few products. Clinical trial data evaluating the effect of rubefacients on acute pain from strains, sprains, sports injuries, and chronic musculoskeletal pain are lacking. A systematic review noted that topical salicylates are effective for pain from acute musculoskeletal conditions, but the low quality of the evidence

| InR, international normalized ratio.
| Combination products that also contain menthol and/or camphor.
led authors to conclude that there are no good data supporting the efficacy of rubefacients.32

Methyl salicylate and trolamine salicylate are topical salicylates. Methyl salicylate is considered a counterirritant, but trolamine salicylate is not considered a counterirritant because it does not produce localized irritation after application. Application of both topical salicylates can lead to systemic effects, especially if the product is applied liberally.33 Repeated application and occlusion with a wrap or bandage also can increase systemic concentrations. Salicylate-containing products should be used with caution in patients in whom systemic salicylates are contraindicated, such as patients with severe asthma or aspirin allergy.33 Topical salicylates have been reported to increase prothrombin time in patients on warfarin and should be used with caution in patients on oral anticoagulants. Methyl salicylate, including oil of wintergreen, is a common source of pediatric poisonings.34 Clinicians should advise patients to keep products out of the reach of children.

The FDA advises that there is insufficient evidence to support the effectiveness of trolamine salicylate.18 However, many patients choose trolamine products because of the lack of medicinal odor.

The group B counterirritants menthol and camphor exert a sensation of cooling through direct action on sensory nerve endings.35 A sensation of warmth follows the cooling effect. The agents also have mild anesthetic activity at low concentrations.35 In higher concentrations, they act as counterirritants and cause a burning sensation by stimulating cutaneous nociceptors. Menthol and camphor are used often in combination with rubefacients.

Menthol, also known as peppermint oil, is used widely in toothpastes, mouthwashes, gum, lozenges, lip balms, and nasal decongestants. For topical analgesic use, it is available in creams, lotions, ointment, and patches. The patches can be trimmed to fit the affected area.

Menthol and camphor should not be used in children younger than 2 years.13 Despite limits on the concentration of available products, camphor can be toxic to children even in small amounts, posing a seizure risk.15 Patients should be advised to keep the products out of the reach of children.

The group C counterirritants methyl nicotinate and histamine dihydrochloride produce vasodilation.36 Methyl nicotinate produces PG-mediated vasodilation.36 NSAIDs and aspirin block the production of PGs and decrease methyl nicotinate–induced vasodilation. Application over a large area has been reported to cause systemic symptoms and syncope, possibly due to vasodilation and a decrease in blood pressure.35 Patients should be educated to apply only scant amounts to the affected area.

The primary counterirritant in group D is capsaicin, a natural substance found in red chili peppers and responsible for the hot, spicy characteristic when used in foods.15,17-20 Capsaicin stimulates the release of substance P from local sensory nerve fibers, depleting substance P stores over time. A period of reduced sensitivity to painful stimuli follows, and transmission of pain impulses to the CNS is reduced.

As with other counterirritants, capsaicin and its derivatives (ie, capsicum and capsicum oleoresin) exert a warming or burning sensation.15,17 With repeated application, desensitization occurs, and the burning sensation subsides. This typically occurs within the first 1 to 2 weeks. After discontinuation, resensitization occurs gradually and returns completely within a few weeks.

Because of the lag time between initiation and effect, capsaicin is not used for treatment of acute pain from injury. Instead, topical capsaicin is used for chronic pain from musculoskeletal and neuropathic disorders. Capsaicin preparations have been studied for treatment of pain from diabetic neuropathy, osteoarthritis, postherpetic neuralgia, and other disorders.39 It is often used as an adjuvant to systemic analgesics in these chronic pain conditions.

Although systemic adverse effects to capsaicin are rare, local adverse effects are expected and common.22,25 Patient education regarding consistent use of capsaicin products is essential to achieving desired outcomes. Product should be applied in a thin layer and rubbed into the skin thoroughly until little remains on the surface.31 Patients using capsaicin should be advised to apply it regularly and consistently three to four times daily and that full effect may take 1 to 2 weeks or longer. Patients should be assured that the burning effects will diminish with repeated application. Adherence to therapy is essential because the burning sensation persists if applications are less frequent than recommended. Because the burning sensation is enhanced with heat, patients should avoid hot showers or baths immediately before or after application. Wearing nitrile gloves during application can decrease the potential for unintended contact with eyes or mucous membranes. Dried product residue has been reported to cause respiratory effects on inhalation, and caution should be used in patients with asthma or other respiratory illnesses.

**Oral Muscle Relaxants**

Where pain is worsened by muscle spasm, oral muscle relaxants serve as a useful adjunct to therapy.29 Antispasmodic agents are preferred over antispastic agents for musculoskeletal pain. The antispasmodic agents include metaxalone, methocarbamol, carisoprodol, and cyclobenzaprine. Muscle relaxants decrease spasm and stiffness associated with either acute or chronic musculoskeletal disorders. These agents should be used with caution because they all may cause sedation, especially in combination with alcohol or opioid analgesics.

**Lifestyle and Behavioral Modifications**

After treatment of the acute injury with RICE and pharmacologic therapy, the final phase of therapy is rehabilitation and prevention of future injury. For most injuries, prolonged
immobilization can lengthen the recovery time by causing wasting of the healthy muscle fibers.\cite{5,10,14} Rehabilitation starts with the development of range of motion via stretching exercises. The patient should warm the muscle first with light activity or moderate heat. Warmth produces relaxation and increases elasticity. Next, the patient should start general strengthening exercises\cite{20} Strengthening and stretching exercises should be continued beyond the healing phase to prevent future injury.

After rehabilitation, the patient should be educated about behavior changes to prevent reinjury or the development of chronic pain.\cite{14,20} The warm-up and strengthening routines learned in the rehabilitation phase should be continued. For overuse injury, correction of biomechanical abnormalities with proper footwear and changes in technique may correct misalignments and imbalances. Repetitive trauma can be decreased with proper training (eg, by implementing a gradual increase in mileage in a running plan).\cite{2,7}

**Patient Care Process**

**Patient Assessment:**
- Assess symptoms. Determine the timing of injury (if applicable), duration, type and degree of pain, and exacerbating factors. Determine if there is interference with usual activities or range of motion.
- Assess exacerbating or alleviating factors. Ask if the patient has tried any nonpharmacologic or pharmacologic treatments.
- Obtain a complete medication history, including prescription and nonprescription drugs and dietary supplement use. Determine whether the patient has used successful or unsuccessful treatments for this condition in the past.
- Gather patient history. Inquire about social history and alcohol use. Ask the patient about drug allergies and chronic health problems such as asthma.
- Assess patient preference for systemic (oral) or local (topical) therapy including acceptability of topical medication with frequent application and/or a medicinal odor.

**Therapy Evaluation:**
- Based on assessment of symptoms, determine whether empirical care or diagnostic evaluation is appropriate.
- If pain and/or swelling are not controlled, determine if pharmacologic therapy is warranted.

**Care Plan Development:**
- Select nonpharmacologic and pharmacologic therapy appropriate for the specific patient (see Tables 60–1 and 60–3; see Figure 60–1).
- Educate the patient on nonpharmacologic therapy, including each of the steps in RICE. If swelling is no longer present, consider heat instead of ice (see Table 60–1).
- Educate on proper use of oral or topical agents selected (see Tables 60–2 and 60–4). If a counterirritant is recommended, counsel patients on the irritant effect of the product and recommend washing hands immediately after use and to avoid heating pads. For patients using a capsaicin product, emphasize adherence.

**Follow-Up Evaluation:**
- If pain is from an acute injury, assess effectiveness within 7 to 10 days. For chronic pain treated with capsaicin, begin to assess pain control in 2 weeks.
- Evaluate for adherence, adverse effects (systemic or local), and drug interactions.
Non-weight-bearing activities, such as swimming or bicycling, can be recommended for initial return to activity.¹³

OUTCOME EVALUATION

- Use a pain scale to monitor treatment interventions to ensure that pain relief is achieved. Ask the patient to rate pain on a scale of zero (no pain) to 10 (worst possible pain) both at rest and with movement. Compare the results with baseline pain assessment to monitor the response to therapy. In pediatric patients, use a visual pain scale with facial expressions depicting various degrees of pain.

- Assess range of motion at baseline and after treatment by comparing movement with the unaffected limb and functionality before the injury. Assess functionality by asking patients if they are able to perform activities of daily living or participate in exercise as desired.

- If pain from acute injury does not decrease greatly within 7 to 10 days, further diagnostic evaluation is warranted.

- For patients using capsaicin products, assess adherence to regular application for therapeutic benefit. Assess chronic pain control in 2 weeks.

- Assess medication adverse effects on a regular basis. When NSAIDs and aspirin are used, ask about GI tolerability, bruising, and bleeding. Inquire about local adverse effects, such as burning, when topical counterirritants are used for treatment.

- Evaluate adherence to preventative rehabilitation measures such as proper footwear, warm-up before activity, strength training, and proper lifting technique.

Abbreviations Introduced in This Chapter

COX Cyclooxygenase
NSAIDs Nonsteroidal anti-inflammatory drugs
PG Prostaglandin

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for the development of primary open-angle glaucoma (POAG) and acute angle-closure glaucoma.
2. Recommend a frequency for glaucoma screening based on patient-specific risk factors.
3. Compare and contrast the pathophysiologic mechanisms responsible for open-angle glaucoma and acute angle-closure glaucoma.
4. Compare and contrast the clinical presentation of chronic open-angle glaucoma and acute angle-closure glaucoma.
5. List the goals of treatment for patients with POAG suspect, POAG, and acute angle-closure glaucoma.
6. Choose the most appropriate therapy based on patient-specific data for open-angle glaucoma, glaucoma suspect, and acute angle-closure glaucoma.
7. Develop a monitoring plan for patients on specific pharmacologic regimens.
8. Counsel patients about glaucoma, drug therapy options, ophthalmic administration techniques, and the importance of adherence to the prescribed regimen.

INTRODUCTION

Glaucoma refers to a spectrum of ophthalmic disorders characterized by neuropathy of the optic nerve and loss of retinal ganglion cells, which typically leads to permanent deterioration of the visual field (peripheral vision) initially and potentially total vision loss (including central vision). It is often, but not always, eye pressure related. Table 61–1 describes the general classification of glaucoma. Glaucoma Suspects are patients with a higher than average risk of developing glaucoma because of the presence of certain clinical findings, family history, or racial background. Glaucoma suspects can be further classified as open-angle glaucoma suspects or angle-closure glaucoma suspects.

Primary open-angle glaucoma (POAG) and primary angle-closure glaucoma (PACG) represent the most common types of glaucoma and therefore are the focus of this chapter. A common presentation of PACG is acute angle-closure crisis (AACC). AACC is the sudden obstruction of the trabecular meshwork, which leads to rapid increases in IOP resulting in pressure-induced optic neuropathy if untreated. Patients with POAG typically have a slow, insidious loss of vision. This is contrasted by the course of AACC, which can lead to rapid vision loss that develops over hours to days.

EPIDEMIOLOGY AND ETIOLOGY

It is estimated that almost 65 million people had glaucoma in 2013, making it the second leading cause of blindness after cataracts. By 2040 this number may increase to greater than 110 million people worldwide. In 2010, glaucoma was the second leading cause of blindness worldwide. In North America it is estimated that almost 3 million people are affected by POAG, and by 2040 this number will increase to 4.2 million. The prevalence varies with race and ethnicity, and it is three to five times more prevalent in African Americans than white Americans. The prevalence of PACG increases with age and is rarely seen in patients younger than 40 years. The prevalence of POAG suspects is difficult to estimate at this time, but it is estimated that 3.5% to 4.5% of white and Hispanic patients older than 40 years have ocular hypertension.

Approximately 20 million people were estimated to have angle-closure glaucoma in 2013, and this is projected to increase to 32 million people by 2040. The prevalence of angle-closure glaucoma is lower than POAG and varies significantly by race and ethnicity. The prevalence is lower in patients of European ancestry (0.4%) but higher in patients of Asian ancestry (1.2%). PACG is also more prevalent with increasing age and among females.

PATHOPHYSIOLOGY

The pathophysiology of glaucomatous neurodegeneration has not been completely elucidated but appears to be caused by both IOP-dependent and IOP-independent factors. Elevated IOP is clearly associated with damage and eventual death of optic nerves; however, optic neuropathy still occurs in patients without elevated IOP which indicates the presence of independent factors that contribute to ganglion cell death. The key to

Data from Refs. 3 and 4.

understanding the pathophysiology and treatment of glaucoma relies on an understanding of aqueous humor dynamics, IOP, and optic nerve anatomy and physiology.

**Aqueous Humor and Intraocular Pressure**

IOP maintains the curvature of the cornea which is important for the refractive properties of the eye. The distribution of IOP in the general population is 10 to 21 mm Hg (1.3–2.8 kPa) and is slightly skewed toward higher values. However, caution should be used in assigning this as the “normal range” for IOP because some patients may have optic neuropathy in the “normal range” while for other patients optic neuropathy may be absent at higher IOPs. Elevated IOP is generally considered greater than 21 mm Hg (2.8 kPa).

Aqueous humor is an optically neutral fluid that provides oxygen and nutrition to the avascular lens and cornea. IOP is dependent on the balance between aqueous humor production and outflow from the anterior segment. (Figures 61–1 and 61–2). The anterior segment of the eye is separated by the iris into the posterior and anterior chambers. The ciliary body, a ring-like structure that surrounds and supports the lens. It also produces aqueous humor through the diffusion and ultrafiltration of plasma. The nonpigmented epithelium of the ciliary body secretes the aqueous humor into the posterior chamber. Aqueous

humor formation can be modified pharmacologically through the α- and β-adrenoceptors, carbonic anhydrase, and sodium and potassium adenosine triphosphatase of the nonpigmented ciliary epithelium.13,14

After secretion, the aqueous humor flows from the posterior chamber through the pupil into the anterior chamber. From the anterior chamber, approximately 80% of aqueous humor then exits through the trabecular meshwork while the remaining 20% exits through the uveoscleral pathway.13,14

The trabecular meshwork is a lattice of connective tissue that surrounds edge of the anterior chamber located in the inside intersection of the edge of the cornea and the iris insertion. The size of the trabecular meshwork can be altered by the contraction or the relaxation of the ciliary muscle. Stimulation of muscarinic receptors on the ciliary muscle causes contraction, which in turn causes the pores of the trabecular meshwork to open, increasing aqueous humor outflow into Schlemm canal and the episcleral venous system.13 The contraction can also be decreased by inhibiting Rho Kinases which are involved in the regulation of the contractile tone of the trabecular meshwork tissue.14

In the uveoscleral pathway, aqueous humor exits the anterior chamber through the iris root and through spaces in the ciliary muscles, which then drain into the suprachoroidal space. Uveoscleral outflow can be pharmacologically modulated by adrenoceptors, prostanoid receptors, and prostamide receptors.13,15

**Optic Nerve**

In the posterior segment of the eye, retinal ganglion cells are responsible for transmitting visual signaling from the retina to the brain. The axons of the retinal ganglion cells converge at the lateral geniculate nucleus in the brain. The optic nerve fiber layer to form the optic nerve. The optic nerve head (also called the optic disc) is the portion of the optic nerve that is visible on funduscopic examination. The optic nerve head is vertically oval and pink to pale yellow with a depression in the center of the optic nerve, called a physiologic cup which is formed as the axons converge and exit the eye as a bundle through the lamina cribrosa. (Figure 61–3). The optic nerve synapses at the lateral geniculate nucleus in the brain.9,10,16,17

**Pathophysiology of Open-Angle Glaucoma**

- In patients with POAG, the cause of elevated IOP is not obvious, as obstruction in aqueous humor outflow is not clinically discernible. Possible causes of this increased IOP may be related to an increase in outflow resistance in the trabecular meshwork.9,10,14,16
- Glaucomatous optic neuropathy may also occur independent of increased IOP. Pressure independent causes of optic neuropathy include abnormal ocular perfusion, oxidative stress, and inflammation.9,16,12,16
- Regardless of the underlying cause, elevated IOP initiates several detrimental changes to glial cells, the lamina cribrosa, and retinal ganglion cells. The increase in IOP can lead to alterations in retinal blood flow and axonal transport of neurotrophic factors, resulting in cellular stress of the retinal ganglion cells. This stress activates the glial cells in a manner that leads to inappropriate remodeling of the extracellular matrix. Elevated IOP deforms the lamina cribrosa, which places mechanical strain on the retinal ganglion cells. Chronic elevation of IOP ultimately causes the retinal ganglion cells to undergo apoptosis.9,10,16,18,19

Current glaucoma therapies fail to target IOP-independent glaucoma pathophysiologic factors. However, IOP reduction may still be beneficial, as the rate of visual field progression is decreased in many patients who exhibit IOP reduction via medical or surgical modalities.9,9

**Pathophysiology of Angle-Closure Glaucoma**

- PACG involves a mechanical obstruction of aqueous humor outflow through the trabecular meshwork by the peripheral iris. Two major mechanisms of trabecular meshwork obstruction by the peripheral iris include pupillary block and an abnormality of the iris called iris plateau. Pupillary block is the more common mechanism of obstruction and results from a complete or functional apposition of the central iris to the anterior lens and is associated with mid-dilation of the pupil. The trapped aqueous humor in the posterior chamber increases pressure behind the iris, causing the peripheral iris to bow forward and obstruct the trabecular meshwork. Plateau iris refers to an anterior displacement of the peripheral iris caused by anteriorly positioned ciliary muscle.

**Patient Encounter, Part 1**

RJ, a 66-year-old African American woman with a history of COPD and hypertension, presents to your clinic for her yearly checkup. She states that she is concerned about losing her eyesight because her older sister has started losing her vision from glaucoma. She denies any changes in her vision.

**Meds:** Tiotropium 18 mcg two inhalations of powder contents of a single capsule; albuterol HFA MDI one to two puffs every 4 to 6 hours as needed; amlodipine 10 mg orally once daily; HCTZ 25 mg orally once daily.

Based on the patient’s medical and family history, what risk factors does this patient have for glaucoma?

How often would you recommend that this patient receive a comprehensive eye evaluation?

What objective assessments should be gathered in order to fully evaluate her risk factors for glaucoma?

How often would you recommend that this patient receive a comprehensive eye evaluation?
processes. In this configuration the peripheral iris bunches as the eye dilates. Both of these mechanisms result in the occlusion of aqueous humor outflow, causing IOP elevation at extreme levels that can lead to vision loss in hours to days.8,10 The degree of iridotrabecular contact (angle closure) can be assessed by visualizing the anatomy of the irido-corneal angle by gonioscopy.

**CLINICAL PRESENTATION AND DIAGNOSIS**

**Risk Factor Evaluation**

For POAG, only 4% to 8% of patients may progress to legal blindness. Vision loss does not occur until there has been significant loss of the retinal ganglion cells. It may take 13 to 16 years for a patient to go blind from glaucoma. A patient’s quality of life may not be affected until significant visual field loss is present and the patient can no longer perform the activities of daily living.2,11 **KEY CONCEPT** Practitioners can play an important role in eye care by assessing patients for risk factors and referring to an eye care specialist for appropriate screening and evaluation. Risk factor evaluation is essential in determining the frequency of comprehensive eye examinations for patients (Table 61–2).

Glaucoma risk factors are also useful in deciding when to start therapy and determining the sequence of pharmacotherapeutic or surgical treatment modalities.2-4 Table 61–3 lists the major risk factors associated with POAG and PACG.

The development of PACG is associated with several anatomical risk factors that lead to shallow anterior chambers. PACG patients may have a thick, anteriorly displaced lens that results from continued growth of the lens and/or cataractous changes. The anterior chamber depth is typically shallower in many individuals with PACG, which predisposes these eyes to anatomically narrower iridocorneal inlets that are a setup for developing critically narrow angles more susceptible to closure (from an enlarging cataractous lens or other insults).1,19

Patients with PACG are characterized by at least 180 degrees of iridotrabecular contact, elevated IOP, and ophthalmic examination characteristic of glaucomatous changes. Recurrent attacks or a prolonged acute attack can lead to the development of peripheral anterior synchiae, which partially obstructs the flow of aqueous humor through the trabecular meshwork.2,19

---

**Clinical Presentation and Diagnosis of POAG**

**General**

- Adult onset (usually greater than 40 years of age)
- Patients may be unaware that they have glaucoma and may be diagnosed during routine eye evaluation
- POAG is usually bilateral with asymmetric disease progression

**Symptoms**

- Patients with severe disease progression may report loss of peripheral vision (“tunnel vision”) and may describe the presence of paracentral, nasal, and arcuate scotoma (blind spots) in their field of vision

**Signs**

- Ophthalmoscopic examination may reveal:
  - Optic nerve head (optic disc) cupping
  - Large cup-to-disc ratio
  - Diffuse thinning, focal narrowing, or notching of the optic nerve head rim
  - Splinter hemorrhages
  - Optic nerve head/nerve fiber layer changes occur before visual field changes can be detected

**Diagnostic Tests**

- Gonioscopy—anterior-chamber angles are to be open
- Applanation tonometry—elevated IOP (greater than 21 mm Hg [2.8 kPa]) may be present. However, patient can have signs of optic neuropathy without elevated IOP
- Pachymetry—measures central corneal thickness. Thin corneas (less than 540 μm) are considered a glaucoma risk factor
- Automated static threshold perimetry—evaluates visual fields. Can detect defects in the visual field before a patient may notice
- Other diagnostic tests—scanning laser polarimetry, confocal scanning laser ophthalmoscopy, and optical coherence tomography
Clinical Presentation and Diagnosis of Acute Angle-Closure Crisis

**General**
- Medical emergency due to high risk of vision loss
- Unilateral in presentation, but fellow eye is at risk

**Symptoms**
- Ocular pain
- Red eye
- Blurry vision
- Halos around lights
- Systemic symptoms may develop:
  - Nausea/vomiting
  - Abdominal pain
  - Headache
  - Diaphoresis

**Signs**
- Cloudy cornea caused by corneal edema
- Conjunctival hyperemia
- Pupil semidilated and fixed to light
- Eye will be harder on palpation through closed eye

**Diagnostic Tests**
- Gonioscopy—anterior-chamber angles will be closed. Peripheral anterior synechiae may be present
- Applanation tonometry—elevated IOP (greater than 21 mm Hg [2.8 kPa], but when symptoms are present, IOP may be greater than 30 mm Hg [4.0 kPa])
- Slit-lamp biomicroscopy—reveals shallow anterior-chamber depth. Signs of previous attacks include peripheral anterior synechiae, iris atrophy, and pupillary dysfunction

### TREATMENT

**Primary Open-Angle Glaucoma**

**Desired Outcomes and Goals**

**Key Concept**: The goals of therapy are to prevent further loss of visual function; minimize adverse effects of therapy and impact on the patient’s vision, general health, and quality of life; maintain IOP at or below a pressure at which further optic nerve damage is unlikely to occur; and educate and involve the patient in the management of their disease. **Key Concept**: Current therapy is directed at altering the flow and production of aqueous humor, which is the major determinant of IOP.

**General Approach**

**Key Concept**: Because POAG is a chronic, often asymptomatic condition, the decision of when and how to treat patients is difficult, as the treatment modalities are often expensive and have potential adverse effects or complications. Currently lowering IOP is the best method to reduce the risk of visual field loss. The clinician should evaluate the potential effectiveness, toxicity, and the likelihood of patient adherence for each therapeutic modality. The ideal therapeutic regimen should have maximal effectiveness and patient tolerance to achieve the desired therapeutic response. The American Academy of Ophthalmology (AAO) publishes Preferred Practice Patterns for POAG and POAG Suspect.

Before the selection of a therapeutic modality, the target IOP should be determined for each patient. The target IOP ideally represents an IOP range that will slow the progression of optic neuropathy and not simply obtain an IOP in the range of 10 to 21 mm Hg (1.3–2.8 kPa). Currently, the initial target IOP is an estimate, but it should be modified based on the progression of the disease at each follow-up visit. **Key Concept**: The AAO recommends an initial target IOP to be set at least 25% lower than the patient’s baseline IOP. The target IOP can be set lower (30%–50% of baseline IOP) for patients who already have severe disease, risk factors for disease progression, or have normal-tension glaucoma (NTG). Risk factors for progression include high IOP, older age, hemorrhage of the optic disc, large cup-to-disc ratio, thinner CCT (central corneal thickness), and established glaucomatous progression (velocity of disease progression is nonlinear).

Initial IOP control can be achieved by medical, laser, surgical, or combination of these therapies. The AAO guidelines do not provide a specific recommendation on which therapeutic modality should be selected first, but patients in the early stages of glaucoma should receive treatment. In general, medical and laser trabeculoplasty are preferred as early treatment options over surgical as surgical interventions are not without potential intraoperative or postoperative complications. The ophthalmologist will individualize therapy based on the risk and benefits for a specific patient. Table 61–4 describes nonpharmacologic treatment modalities for POAG.

Medical treatment is the most commonly selected therapeutic modality. A well-tolerated ocular antihypertensive, at the lowest concentration, should be selected as the initial mediation (Table 61–5). The ocular hypotensive lipids are preferred first-line agents since they are the most effective at lowering at IOP of both peak and trough measurements by at least 25% of baseline.

(Continued)
IOP.\textsuperscript{25–29} Additionally, these agents lack systemic side effects and are dosed once daily. If monotherapy alone lowers IOP but does not reach target pressure or there is evidence of progression, then combination therapy or switching to another agent is appropriate. The addition of a second agent from another class generally has an additive effect on IOP reduction. The ocular hypertensive lipids, timolol, carbonic anhydrase inhibitors, or brimonidine are reasonable choices for addition as a second agent.\textsuperscript{3,9,12} Combination eye-drops reduce the number of drops that need to be administered. Increasing the concentration or dose frequency can also be tried when possible. Adverse effects can be caused by an eye drop’s therapeutic agent or inactive excipients, such as preservatives. Benzalkonium chloride is a common eye drop preservative which has been associated with superficial punctate keratitis, corneal erosion, and conjunctival allergy. Intolerances to preservatives can be resolved by changing to a preservative-free eye drop.\textsuperscript{30} Figure 61–4 presents an algorithm to select and optimize POAG treatment.

A uniocular trial can be used to assess the safety and effectiveness of a topical medication before initiation in both eyes; however, uniocular drug trials do not always predict the IOP response of the second eye. Ideally, the effectiveness of a medication should be assessed independently using baseline IOP measurements.

\section*{Treatment Considerations for POAG Suspects}

POAG suspects should be considered for topical medication therapy if they are at high risk for developing POAG or have a high IOP in which glaucomatous nerve damage is likely to occur. POAG suspects that develop evidence of glaucomatous damage or visual field defect have developed POAG and should be treated accordingly.\textsuperscript{2} The Ocular Hypertension Treatment Study (OHTS) demonstrated that a 20% decrease in IOP can reduce the progression from ocular hypertension to POAG over a 5-year period. The incidence of progression to POAG in the treatment (4.4%) and control (9.5%) groups was small, which underscores the importance of selecting patients at high risk of progressing to POAG.\textsuperscript{21} When medical therapy is indicated, a well-tolerated agent should be selected and optimized following the POAG treatment algorithm (see Figure 61–4). The benefit of therapy should be reassessed in patients who may require third- or fourth-line agents to control IOP. Surgical or laser intervention are rarely indicated in the treatment of glaucoma suspects.\textsuperscript{2}

\section*{Primary Angle-Closure Glaucoma}

\subsection*{Desired Outcomes and Goals}

Therapeutic modalities for PACG are targeted at decreasing IOP. The goals of therapy are to preserve visual function by controlling the elevation in IOP, prevent damage to the optic nerve, and manage or prevent an acute attack of angle closure.\textsuperscript{4}

\subsection*{General Approach}

\textbf{Key Concept} Acute angle-closure crisis is a medical emergency and requires urgent laser or surgical intervention. The treatment of choice for PACG is peripheral laser iridotomy. Laser iridotomy uses laser energy to cut a hole into the iris to alleviate the aqueous humor buildup behind the iris, resulting in reversal of appositional angle closure. Patients currently experiencing an acute angle-closure crisis should receive medical therapy to lower IOP, reduce pain, and reverse corneal edema before the iridotomy. IOP should first be lowered with topical β-blockers, topical α-agonist, prostaglandin F\textsubscript{2α} analogue, systemic carbonic anhydrase inhibitors, or hyperosmotic agents. Once the IOP has been controlled,
SECTION 12 | DISORDERS OF THE EYES, EARS, NOSE, AND THROAT

Contraindications?

Alternative first-line agent: prostaglandins or brimonidine

If contraindication to first-line agents, use topical CAI

Inadequate response
• Ensure compliance
• Instruct patient on nasolacrimal occlusion if not currently used
• Increase concentration (if possible) or increase dose frequency
• Switch to alternative first-line agent if no response, add second first-line agent if partial response

Intolerance
• Reduce concentration if possible OR
• Change formulations OR
• Switch to class alternative OR
• Switch to alternative first-line agent

Inadequate response to monotherapy
• Ensure compliance
• If no response, sequentially try alternative first-line topical agents OR
• If partial response, add second or third first-line agent or topical CAI, or unoprostone (multidrug regimens containing two to four agents may be required)

Intolerance
• Reduce dose/concentration if possible OR
• Change formulations OR
• Switch to class alternatives OR
• Switch to alternative combination

Inadequate response to first- and second-line topical combination therapy
• Ensure compliance
• Consider adding direct-acting cholinergic agent (fourth line), and if necessary, replace with a cholinesterase inhibitor
• Consider adding oral carbonic anhydrase inhibitor in place of topical carbonic anhydrase inhibitor
• Multiple topical therapies plus oral carbonic anhydrase inhibitor may be necessary

Intolerance
• Reduce dose/concentration if possible OR
• Change formulations OR
• Switch to class alternatives OR
• Switch to alternative combination

Intolerance or inadequate response maximally tolerated combination drug therapy

Laser or surgical procedure

Assess response in 2–4 weeks

FIGURE 61–4. Algorithm for the pharmacotherapy of open-angle glaucoma. Footnotes:
*Fourth-line agents not commonly used any longer.
Most clinicians believe laser procedures should be performed earlier (eg, after three-drug maximum, poorly adherent patient).
miotics (ie, pilocarpine) can be used to break the pupillary block. A topical IOP-lowering agent should be continued to control IOP until laser iridotomy can be performed. Corneal indentation with a cotton-tipped applicator or gonioscopic lens may break pupillary block. If laser iridotomy cannot be performed, then surgical incisional iridectomy is used. Incisional iridectomy is the surgical removal of a small portion of the peripheral iris to allow flow of aqueous humor trapped in the posterior chamber to migrate to the anterior chamber (bypassing the normal flow pattern through the pupil). Topical corticosteroid may be employed to decrease inflammation postoperatively. The fellow eye is at high risk to develop an acute attack and should receive prophylactic iridotomy within a reasonable interval of time. Lens extraction surgery may be another treatment modality as it increases the anterior chamber depth. PACG patients may require chronic medical therapy if the patient has PACG superimposed on pre-existing POAG or if synechia formation causes reduced outflow with a continued increase in IOP.9,20

**Pharmacologic Therapy**

▶ **β-Adrenergic Antagonists**

- Topical β-adrenergic antagonists (β-blockers) are now considered a second-line agent after the prostaglandin analogues for the treatment of POAG unless contraindications are present.23,28 Topical β-blockers decrease IOP by reducing the formation of aqueous humor made by the ciliary body, which results in a 20% to 35% reduction in IOP.28,29,32,33 Timolol, levobunolol, metipranolol, and carteolol are nonselective for β1- and β2-adrenergic receptors, whereas betaxolol has β1-selective properties.23,33 Betaxolol reduces IOP to a lesser extent than the nonselective β-blockers, but part of its efficacy may be related to a neuroprotective mechanism of independent IOP reduction.24

- Topical β-blockers are typically administered twice daily. A gel-forming solution of timolol (Timoptic-XE) can be administered once daily. Tachyphylaxis may occur in 20% to 50% of patients on monotherapy with a β-blocker, resulting in the need for a different agent or combination therapy. Patients on concurrent systemic β-blockers may experience less IOP reduction than patients on only topical β-blockers.32,33

- β-Blockers can cause significant systemic adverse effects through nasolacrimal drainage and subsequent systemic absorption in the mucous membranes in the nasal-pharyngeal cavity. This route bypasses first-pass hepatic metabolism resulting in pharmacologically significant serum drug concentrations.35 Bronchospasm is the most common pulmonary effect of topical β-blockers. Pulmonary edema, status asthmaticus, and respiratory arrest have been reported with β-blockers as well. Cardiovascular effects include bradycardia, hypotension, and congestive heart failure exacerbation. As with systemic β-blockers, topical β-blockers have also been reported to cause depression and hyperlipidemia and mask symptoms of hypoglycemia. The β2-selective properties of betaxolol may cause less exacerbation of pulmonary disease. Despite the intrinsic sympathomimetic activity demonstrated by carteolol, this does not translate to a clinically significant decrease in pulmonary or cardiovascular adverse effects. Topical β-blockers are generally contraindicated in patients with asthma, chronic obstructive pulmonary disease (COPD), sinus bradycardia, second- or third-degree heart block, cardiac failure, and hypersensitivity to the product.30,33,35

Stinging of the eyes upon instillation is the most common adverse effect. Other local adverse effects include conjunctivitis, keratitis, dry eyes, and uveitis.30,32

- Patients prescribed topical β-blockers should be counseled on the nasolacrimal occlusion technique to decrease systemic absorption.

▶ **Ocular Hypotensive Lipids**

- The ocular hypotensive lipids in typical ophthalmology practice are considered first-line agents along with β-blockers because of their superior efficacy and safety profiles. Many clinicians may choose to use the ocular hypotensive lipids as first line, especially in patients who have an initial requirement to lower IOP by greater than 25%.28,29,32,33 All four of the available agents currently have an FDA indication for both POAG and ocular hypertension. Latanoprost and travoprost have dosing aids that help patients administer each medication. Travoprost and tafluprost are available as benzalkonium chloride–free solutions. Latanoprost, travoprost, tafluprost are analogues of prostaglandin F2α and are agonists of the prostanoid FP receptor, which appears to lower IOP by increasing aqueous humor outflow through the uveoscleral pathway. Bimatoprost is a prostamide analogue and appears to lower IOP by activating prostamide receptors in the uveoscleral pathway and possibly through increasing outflow through the trabecular meshwork. The exact mechanism of how uveoscleral outflow is increased is still unclear, but stimulation of prostanoid FP receptors and prostamide receptors in the ciliary body cause remodeling of the extracellular matrix, making it more permeable to aqueous humor, thus increasing aqueous humor outflow through the ciliary muscles.32,36,37

- The ocular hypotensive lipids are administered once daily at bedtime and should not be increased to twice daily, as this may decrease effectiveness. The ocular hypotensive lipids can provide a consistent reduction in IOP over a 24-hour period.35 For patients nonresponsive to latanoprost, switching to bimatoprost may allow some patients to reach their IOP goal, presumably because of the proposed difference in the site of action of each drug.38,39

- The ocular hypotensive lipids are well tolerated and rarely cause systemic side effects (headache has been reported). Local effects include conjunctival hyperemia, stinging on instillation, increase in iris pigmentation, deepening of the upper eyelid sulcus, hypertrichosis, and darkening of the eyelashes. Increases in iris pigmentation occur most commonly in patients with multicolored irides on long-term prostaglandin analogue therapy. The mechanism of this effect is by its action on melanocytes of the iris, in which the irides become darker because of increased production of melanin in the iris.35 Increased iris pigmentation appears to be only a cosmetic effect but may affect your product selection, especially when choosing monocular therapy. Conjunctival hyperemia or engorgement of conjunctival blood vessels is a common adverse effect caused by a vasodilatory effect on scleral blood vessels. It is most prominent early in therapy and usually subsides over time. Although generally a benign adverse effect, patients may have a concern if it affects their cosmetic appearance.30,32

- The ocular hypotensive lipids should be used with caution in patients, since they may worsen anterior uveitis and herpetic keratitis. Cystoid macular edema has been reported during treatment with the ocular hypotensive lipids; therefore, use caution in patients with intraocular inflammation, aphakic patients, pseudophakic patients with a history of intraoperative complications (eg, torn posterior lens capsule), or in patients with risk factors for macular edema.30

- Patients prescribed ocular hypotensive lipids should be counseled on potential adverse effects and appropriate
administration. Patients receiving latanoprost or tafluprost should be instructed to refrigerate unopened medication. Once open latanoprost can stored at room temperature for 6 weeks. Tafluprost single-use containers can be stored at room temperature for up to 28 days.

► **α₂-Adrenergic Agonists**

Brimonidine and apraclonidine are α₂-adrenergic agonists that decrease IOP by reducing aqueous humor production. Brimonidine has a higher selectivity to the α₂-receptor than apraclonidine and has a dual mechanism of action by increasing uveoscleral outflow.²²,²³ Apraclonidine is often used for the prevention and treatment of postsurgical IOP elevations and is no longer commonly used for long-term treatment of POAG because of tachyphylaxis and high rate of blepharoconjunctivitis. Brimonidine lowers IOP by 14% to 25%. Peak IOP-lowering effect is similar to that of timolol, but the trough IOP-lowering effect is less than that of timolol.²²,²³ Brimonidine may exhibit a neuroprotective effect and has been shown to delay visual field progression compared with timolol but there is insufficient evidence it prevents retinal ganglion cell death.⁴⁰

Brimonidine is typically used as an adjunctive agent in combination with other agents and is usually administered every 8 hours. A 12-hour dosing schedule may be employed when used in combination therapy. Brimonidine-purre 0.1% and 0.15% solution (Alphagan-P) has similar efficacy compared with the brimonidine 0.2% solution, because the purite solution’s higher pH allows for more drug to penetrate the cornea.²²,²³ Brimonidine cause both local and systemic effects. Local effects include blepharoconjunctivitis, conjunctivitis, and ocular allergy. Systemic effects include headache, dry mouth, and fatigue.³⁰,³²,³³ The frequency of dosing and local adverse effects may lead to nonadherence in some patients. Patients prescribed brimonidine should be counseled on the nasolacrimal occlusion technique to reduce systemic adverse effects and to improve efficacy.³²,³³

► **Carbonic Anhydrase Inhibitors**

Carbonic anhydrase inhibitors decrease aqueous humor production by inhibition of the carbonic anhydrase isoenzyme II located in the ciliary body. In the eye, carbonic anhydrase catalyzes the conversion of H₂O and CO₂ to HCO⁻³ and H⁺, which is a significant step in aqueous humor production. Carbonic anhydrase inhibitors are available in systemic and topical preparations.²²,²³

**Topical Carbonic Anhydrase Inhibitors** Dorzolamide and brinzolamide are the only topical carbonic anhydrase inhibitors available on the market. Both medications are administered every 8 hours and are used as adjunctive therapy or as monotherapy for patients who cannot tolerate first-line therapies. Nasolacrimal occlusion may allow for an every-12-hour dosing interval. They lower peak and trough IOP by 17% to 20%.²²,²³,²⁹,³²,³³

Local side effects include burning, stinging, itching, foreign body sensation, dry eyes, and conjunctivitis. Brinzolamide may have fewer incidences of these side effects since the drug is in a neutral pH solution. Dorzolamide has been reported to cause irreversible corneal decompensation. Taste abnormalities have been reported with each agent. Both topical carbonic anhydrase inhibitors are sulfonamides and are contraindicated in patients with history of sulfonamide hypersensitivity.³⁰,³²,³³

**Systemic Carbonic Anhydrase Inhibitors** There are three systemic carbonic anhydrase inhibitors: acetazolamide, dichlorphenamide, and methazolamide. These agents effectively lower IOP by 20% to 30% but are reserved as third-line to fourth-line agents because of their significant adverse effects. They are typically used as bridge therapy from maximal medical therapy to laser or surgical intervention or to control IOP in the perioperative period following a laser or surgical ocular procedure. The systemic carbonic anhydrase inhibitors can also be used to lower IOP in acute angle-closure glaucoma. Acetazolamide has an IV formulation that can be used in patients who are experiencing nausea due to the angle-closure attack. Acetazolamide and methazolamide are the best tolerated of the three agents.³²,³³

The systemic carbonic anhydrase inhibitors are associated with significant adverse effects that include paresthesias of the hands and feet, nausea, vomiting, and weight loss. Patients can develop systemic acidosis, hypokalemia, hyponatremia, and nephrolithiasis due to the inhibition of renal carbonic anhydrase. Sulfonamide allergy, renal failure, hepatic insufficiency, COPD, and decreased serum potassium and sodium levels are all contraindications of systemic carbonic anhydrase inhibitor therapy. Blood dyscrasias from bone marrow suppression have been reported and include agranulocytosis, aplastic anemia, neutropenia, and thrombocytopenia.³²,³³

► **Cholinergic Agents**

Cholinergic agents (also called parasympathomimetics or miotics) were the first class of agents to treat glaucoma. The class can be divided into direct-acting and indirect-acting cholinergic agents.

**Direct-Acting Cholinergic Agents** Pilocarpine directly stimulates the muscarinic (M₂) receptors of the ciliary body, which causes contraction of the ciliary muscle. This results in the widening of spaces in the trabecular meshwork, which causes an increase in aqueous humor outflow and reduces IOP by 20% to 30%.

Pilocarpine requires administration four times daily, since the IOP-lowering effect lasts only 6 hours. Pilocarpine is available in 1%, 2%, and 4% concentrations. Higher concentrations may be needed for patients with dark irides to obtain adequate IOP reduction. A pilocarpine 4% gel is available and allows for once-daily dosing at bedtime.³³ Pilocarpine is considered a fourth-line agent for POAG. In the treatment of PACG, it is important to delay use until IOP has been controlled, because pilocarpine could worsen angle closure by causing anterior displacement of the lens. Once IOP is controlled, pilocarpine can be given to break pupillary block by instilling one drop applied twice in an hour.

---

**Patient Encounter, Part 2**

RJ was referred to an ophthalmologist for a comprehensive eye evaluation. The ophthalmology report reveals the patient has an IOP (as assessed by applanation tonometry) of 19 mm Hg (2.5 kPa) in the right eye and 23 mm Hg (3.1 kPa) in the left eye. Gonioscopic examination reveals open anterior angles in both eyes. Gonioscopy reveals cupping of the optic discs in both eyes. Visual field examination reveals a nerve fiber bundle defect consistent with glaucoma in the left eye.

**What is your assessment of this patient’s glaucoma type?**

**What pharmacologic and nonpharmacologic treatment modalities are available for this patient?**
The adverse effects of pilocarpine are caused by the induction of miosis. The contraction of the ciliary muscle causes the lens to displace forward, which can lead to accommodation spasm and myopia, and can lead to brow ache. Pupillary constriction can also affect night vision. Pilocarpine should be avoided in patients with severe myopia as it increases the risk of developing retinal detachment. Systemic effects may occur at higher concentrations and include nausea, vomiting and diarrhea, and bradycardia.

- Carbachol stimulates the same muscarinic receptor as pilocarpine and also inhibits acetylcholinesterase, the enzyme that metabolizes acetylcholine. Carbachol is more potent than pilocarpine, but it causes more accommodation spasm and brow ache and may also cause anterior uveitis. Other reported side effects include corneal clouding, persistent bullous keratopathy, and retinal detachment. Carbachol is rarely used today because of the side-effect profile.

**Indirect-Acting Cholinergic Agents**

Echothiophate iodide and demecarium bromide inhibit acetylcholinesterase. Inhibition of this enzyme increases the availability of acetylcholine at the nerve junction, thus increasing the stimulation of the muscarinic (M) receptors of the ciliary body. These products are given twice daily and have similar efficacy to pilocarpine in the degree of IOP reduction. The side-effect profile is similar to that of pilocarpine; however, they can deplete systemic cholinesterases and pseudocholinesterases and may cause the formation of cataracts. These agents should be discontinued at least 1 week before general surgical procedures. Succinylcholine and some local anesthetics are metabolized by pseudocholinesterases; therefore, depletion of this enzyme by echothiophate or demecarium may lead to toxic effects. These agents are typically used when other topical agents have failed and are limited to patients who have had their lenses removed or who have artificial lenses.

**Hyperosmotics**

Glycerin, isosorbide, and mannitol are hyperosmotic agents that increase the osmolality of blood. These agents create an osmotic gradient that draws water from the vitreous humor, thus decreasing IOP. The resulting dehydration of the vitreous humor may cause posterior movement of the lens, which then causes the anterior chamber to deepen, thus opening the anterior angle. If the patient is not vomiting, glycerin (1–2.5 g/kg of a 50%) solution and isosorbide (1.5–2 g/kg) can be given orally. Isosorbide is preferred in patients with diabetes because it is not metabolized into glucose. If the patient has nausea or vomiting, mannitol (20%) can be given IV at a dose of 1 to 2 g/kg over 45 minutes. The hyperosmotic agents are rapid acting, reaching peak effect in 30 to 60 minutes. Headache and thirst are common complaints. Patients who are already dehydrated are at risk of developing CNS dehydration, which can lead to coma. These agents should be used with caution in patients with renal or cardiovascular disease, as extracellular water is increased.

**Nonselective Adrenergic Agonists**

Epinephrine and its prodrg, dipivefrin, are rarely used for the treatment of glaucoma and are considered last-line agents because of their systemic side-effect profile. Dipivefrin increases the corneal penetration. Once it is absorbed through the cornea, it is enzymatically cleaved to epinephrine. Epinephrine has α- and β-agonist activity and is thought to increase the outflow of aqueous humor through the trabecular meshwork and the uveoscleral pathway. Both products are instilled twice daily and reduce IOP by 15% to 25%. Local adverse effects include mydriasis, conjunctival hyperemia, and ocular irritation. Aphakic patients should not use these medications because they cause a reversible cystoid macular edema. Epinephrine and dipivefrin should not be used in patients with narrow angles since these agents can cause acute angle closure. Systemic side effects include palpitations, increased blood pressure, and arrhythmia, and therefore, these drugs should be used with caution in patients with cardiovascular disease, cerebrovascular disease, and hyperthyroidism. Using the nasolacrimal technique may decrease systemic effects.

**SPECIAL CONSIDERATIONS: DRUG-INDUCED GLAUCOMAS**

Medications have the potential to cause or exacerbate both POAG and PACG; however, PACG is more likely to be exacerbated by medications than POAG. The use of medications with anticholinergic or sympathomimetic properties can precipitate angle closure. Medications with anticholinergic properties include first-generation antihistamines, tricyclic antidepressants, and antipsychotics. Medications with sympathomimetic properties include phenylephrine and pseudoephedrine. PACG patients who have been treated with laser iridotomy can usually use these agents without causing an exacerbation. Sulfa-based drugs, such as tobramycin, acetazolamide, and hydrochlorothiazide, cause swelling of the ciliary body, which causes an anterior displacement of the lens, resulting in a decrease in anterior-chamber depth. Patients with open or closed anterior angles can experience elevated IOP from these drugs. Controlled POAG is rarely exacerbated by anticholinergics and sympathomimetics unless the patient is concomitantly at risk for angle closure. For uncontrolled or untreated POAG, the risk–benefit ratio should be considered before employing these agents. POAG can be exacerbated by any administered form of corticosteroids. Corticosteroids increase IOP by causing obstruction of the trabecular meshwork with extracellular material. The increase in IOP appears to increase with potency and intraocular penetration. Ophthalmic corticosteroid preparations carry the highest risk of increasing IOP. However, all administered routes have been shown to raise IOP in some patients. The onset and extent of IOP elevation is dependent on the specific corticosteroid, dose, route, and frequency. Generally corticosteroid-induced IOP elevation typically occurs within a few weeks of beginning steroid therapy. In most cases, the IOP lowers spontaneously to the baseline within a few weeks to months upon stopping the steroid. In rare instances, the IOP remains elevated. Some patients exhibit clinically significant and dangerously high IOP as a result of steroid use.
**Application of Ophthalmic Solutions or Suspension**

1. Clean hands with soap and water.
2. Avoid touching the dropper tip with your fingers or against your eye to maintain sterility of product; shake dropper bottle if product is a suspension.
3. Tilt head back; pull down the lower eye lid with index finger.
4. Hold the dropper bottle with other hand as close as possible without touching the eye. The dropper should be pointing toward the eye with remaining fingers bracing against the face.
5. Gently squeeze the bottle so that one drop is placed into the pocket.
6. Close your eye for 2 to 3 minutes to allow for the maximum corneal penetration of drug.
7. Use a tissue to wipe away any excess liquid.
8. Replace and retighten the cap to the dropper bottle.
9. Wait at least 5 minutes before instilling another ophthalmic drug preparation.
10. Application of some ophthalmic preparations (suspension and gels) may cause blurring of vision.

**OUTCOME EVALUATION**

**Primary Open-Angle Glaucoma**

Evaluate patients 2 to 4 weeks after the initiation or alteration of medical therapy. The clinician should elicit the status of ocular health since the last visit, systemic medical history, medication history, and presence of local and ocular adverse effects of medications. IOP measurement, visual acuity assessment, and slit-lamp biomicroscopy at every POAG follow-up visit is necessary. The frequency of visual fields and optic nerve evaluation depends on whether IOP is controlled, the length of time IOP has been controlled, and whether there is progression of the disease. Patients who are at target IOP and have no disease progression should have optic nerve head evaluation and visual field testing every 6 to 12 months. Patients with disease progression and/or who are not at target IOP should receive follow-up evaluation every 1 to 6 months. Assess the patient’s ability to use topical eye drops. See Application of Ophthalmic Solutions or Suspensions. Finally, evaluate the patient’s adherence to their medical regimen. Nonadherence among patients on topical medical therapy ranges from 5% to 80%. Suspect nonadherence in patients who have visual field and optic nerve progression despite a low IOP measurement, as patients may be more adherent to their medical regimen before their visit. Pharmacy refill histories may be useful in assessing adherence but do not confirm that the patient is actually taking the regimen as prescribed. Specific patient factors related to the risk of nonadherence may include health literacy, medication cost, complicated medication regimens, adverse effects, and ethnicity. Using adherence aids, prescribing the least complex regimen, and educating patients about their glaucoma are ways to reduce nonadherence.

**Care Plan Development:**

- Select medication therapy that will likely achieve goal IOP with minimal adverse effects.
- Use combination glaucoma eye drops when possible to improve adherence.
- Address patient concerns about glaucoma and its treatment.
- Educate patient on importance of medication adherence. Instruct patient on how to instill eye drops and have them demonstrate their technique.

**Follow-Up Evaluation:**

- Follow-up in 2 to 4 weeks to reassess patient for progression in glaucomatous damage, achievement of target IOP, adherence, and presence of adverse effects to medication therapy. Review interval medical history. Perform/Review ophthalmic examination findings.

**Patient Care Process**

**Patient Assessment:**

- Determine whether the patient is experiencing difficulty with vision.
- Review medical and family history. Does the patient have risk factors for glaucoma (Table 61–3)? Review patient’s prescription, nonprescription, and natural product use. Does the patient have any causes for drug-induced glaucoma? Does the patient take any medications that interact with any glaucoma medication? Perform/review diagnostic tests (IOP, visual acuity, gonioscopy, visual fields, optic nerve evaluation, etc).

**Therapy Evaluation:**

- If glaucomatous damage is present or has progressed, determine if medication therapy is indicated.
- If patient is already receiving medication therapy, assess efficacy, safety, and patient adherence. Can the patient appropriately use prescribed ophthalmic preparations? Are there factors contributing to poor adherence? Does the patient report or exhibit signs or symptoms for systemic and ocular adverse drug reactions?
Primary Angle-Closure Glaucoma

Follow-up of acute angle-closure crisis occurs in the postoperative period. Evaluate the patency of the iridotomy and IOP in the postoperative period. Perform gonioscopy and optic nerve head evaluation if not already performed. Stable patients with PACG should be evaluated at least annually, specifically for the presence of peripheral anterior synechia and optic neuropathy. Treat patients according to POAG guidelines if they have underlying POAG or areas of peripheral anterior synechia with the presence of optic neuropathy.

Abbreviations Introduced in This Chapter

AAO American Academy of Ophthalmology
CCT Central corneal thickness
IOP Intraocular pressure
NTG Normal tension glaucoma
PACG Primary angle-closure glaucoma
POAG Primary open-angle glaucoma

REFERENCES

INTRODUCTION
This chapter provides an overview of common ophthalmic disorders and their treatments. Many ophthalmic disorders are benign or self-limited, but the clinician must be able to distinguish conditions that lead to serious morbidity, including blindness. Preserving both visual function and cosmetic appearance is the goal. The clinician must understand when referral is appropriate and the proper time frame for follow-up, based on the patient-specific condition.

OCULAR EMERGENCIES
Etiology and Epidemiology
Ophthalmic problems encompass 3% of all emergency department visits. Corneal abrasions are the most common eye injury in children. Scratches, objects and aggressive eye rubbing may damage the cornea. Healthcare practitioners must know the proper treatment for ocular emergencies and the time frame for follow-up in order to prevent further morbidity (Table 62-1).

CORNEAL ABRASIONS
Treatment
▶ Desired Outcomes
• Complete healing of the corneal abrasion with no scarring or vision impairment
• Prevent infection and pain
• Prevent corneal loss or corneal transplant

▶ General Approach to Treatment
The five layers of the cornea contain no blood vessels but are nourished by tears, oxygen, and aqueous humor. Minor corneal abrasions heal quickly. Moderate abrasions take 24 to 72 hours to heal. Deep scratches may scar the cornea and require corneal transplant if vision is impaired. Do not use eye patches to treat uncomplicated corneal abrasion.

Table 62–1
Corneal Abrasion Prevention
• Wear eye protection during sports
• Wear industrial safety lenses
• Carefully fit and place contact lenses

▶ Pharmacologic Therapy

Topical NSAIDs
Topical nonsteroidal anti-inflammatory drugs (NSAIDs) decrease pain from corneal abrasion. Available ocular NSAIDs are bromfenac 0.09%, diclofenac 0.1%, ketorolac 0.5%, and nepafenac 0.1%. The usual dose for diclofenac and ketorolac is one drop four times daily; nepafenac is dosed three times daily, and bromfenac is dosed twice daily. Use topical NSAIDs with caution in patients with clotting disorders or those who are on systemic NSAIDs or warfarin therapy. Oral analgescs may be an option for some patients.

Topical Antibiotics
Infection slows the healing of a corneal abrasion; therefore, prophylactic antibiotics are often used. Discontinue the use of contact lenses until the abrasion is healed and the antibiotic course complete. In contact lens wearers, choose an antibiotic that covers Pseudomonas aeruginosa, like gentamicin ointment or solution or a fluoroquinolone.

Outcome Evaluation
1. Reevaluate patients in 24 hours.
2. If symptoms worsen, recheck for foreign bodies.
3. If not fully healed, evaluate again in 3 to 4 days.
4. Refer to ophthalmologist if:
   • Abrasion greater than 4 mm
   • Contact lens wearers
   • Decreased vision
   • Lack of improvement or worsening symptoms
### OTHER OCULAR EMERGENCIES: TREATMENT

#### Traumatic Injuries

Attempt to remove loose foreign bodies by gentle irrigation with artificial tears or sterile saline. If removal is successful, a topical broad-spectrum antibiotic, such as erythromycin, will prevent infection. If irrigation is unsuccessful, only ophthalmologists should complete mechanical removal of foreign objects. Protect the eye from further injury with a metal eye shield or a paper cup taped over the eye while awaiting the ophthalmologist.\(^4\)

#### Splash Injuries and Chemical Exposure

Instruct patients by phone to immediately irrigate the eye with water or saline continuously for at least 15 minutes before seeking a clinician. Irrigation dilutes and removes the chemical agent and is the best way to decrease ocular tissue damage. Patients should then seek immediate care from an ophthalmologist or emergency facility.\(^4\)

#### Loss of Vision

A variety of disorders may lead to rapid, painless, monocular, or binocular vision loss. These include central retinal artery occlusion, acute narrow-angle glaucoma, trauma, and others.\(^5\) The differential diagnosis is complex and should be undertaken by an emergency department or ophthalmologist.

#### CONJUNCTIVITIS

### Etiology

Conjunctivitis, also known as red eye, is one of the most common ophthalmic complaints seen by clinicians. An inflamed conjunctiva is the most common cause of red eye.\(^6\) Conjunctivitis cases are mostly viral in nature. Use the differential diagnosis algorithm shown in Figure 62–1 to determine the proper treatment or need for referral.

#### BACTERIAL CONJUNCTIVITIS

### Etiology and Pathophysiology

The primary cause of acute bacterial conjunctivitis (ABC) is gram-positive organisms, including *Streptococcus pneumoniae* and *Staphylococcus aureus*, and gram-negative *Haemophilus influenzae*.\(^6\) Both acute and chronic bacterial conjunctivitis are self-limiting except if caused by *Neisseria*.\(^6\) The pathogens are rarely cultured unless the case is unresponsive to treatment.\(^6\)

Patients with bacterial conjunctivitis lasting 4 weeks or more should be referred to an ophthalmologist.\(^7\)

Hyperacute bacterial conjunctivitis is associated with gonococcal ( *Neisseria gonorrhoeae* or *Neisseria meningitides*) infections in sexually active patients. Prompt workup and treatment is required, as corneal perforation can occur.\(^6\)\(^7\)

### Treatment

#### Desired Outcomes

- Complete resolution of the bacterial conjunctivitis
- Prevent adverse consequences of the infection
- Preserve functionality of the eye

#### General Approach to Treatment

- ABC may be treated with broad-spectrum antibiotics. Although the condition is usually self-limiting, antibiotic treatment decreases the spread of disease to others and prevents extraocular infection. Additionally, treatment may help decrease the risk of corneal ulceration or other complications that affect sight. Finally, treatment speeds recovery.\(^6\)\(^7\)

#### Pharmacologic Therapy

- The choice of an antibiotic agent for ABC is largely empiric. The initial treatment needs to include *Staphylococcus* coverage, and cost and side-effect profile may be pertinent.\(^6\) In general, ointments are a good dosage form for children. Adults may prefer drops because they do not interfere with vision. Many broad-spectrum topical antibiotics are approved to treat ABC (Tables 62–2 and 62–3).
- First-line treatments include polymyxin B/trimethoprim solution, polymyxin B with bacitracin ointment, or erythromycin ointment
- The aminoglycosides (tobramycin and gentamicin) are alternatives but have incomplete gram-positive coverage and can cause corneal epithelial toxicity\(^7\)

### Clinical Presentation and Diagnosis of Corneal Abrasions\(^3\)

#### Symptoms

- Photophobia
- Pain with extraocular muscle movement
- Foreign body sensation (or gritty feeling)
- Recent ocular trauma

#### Signs

- Excessive tearing
- Blepharospasm
- Blurred vision

#### Diagnostic Test

Use sterile fluorescein dye strips and visualize the cornea under a cobalt-blue filtered light; abrasions appear green; ensure that no foreign body remains in the eye.

</tbody>
</table>

---

**Outcome Evaluation**

- Significant improvement of acute bacterial conjunctivitis should be seen within 1 week. 

---

- Sulfacetamide has significant resistance
- If infection recurs or is severe, use a topical fluoroquinolone
- Treat hyperacute bacterial conjunctivitis with a single dose of intramuscular ceftriaxone 1 g in combination with topical antibiotics and refer the patient to an ophthalmologist
- If concurrent blepharitis is present, add a lid hygiene regimen to antibiotic treatment

---

**VIRAL CONJUNCTIVITIS**

**Etiology**

Viral conjunctivitis is commonly caused by adenovirus and is often called "pink-eye." Adenovirus is easily spread through swimming pools, camps, and contaminated fingers and medical instruments. Patients often present with an upper respiratory tract infection or recent exposure to viral conjunctivitis.

**KEY CONCEPT** Viral conjunctivitis is usually self-limiting, resolving within 2 weeks.

**Treatment**

- **Desired Outcomes**
  - Complete resolution of the viral conjunctivitis
  - Prevent adverse consequences of the infection
  - Avoid spreading infection to other patients

- **Nonpharmacologic Therapy**
  - Nonpharmacologic measures are critical to prevent the spread of viral conjunctivitis. Cold compresses may relieve symptoms. Patients should not share towels or other contaminated objects, should avoid close contact with other people, and avoid swimming for 2 weeks. Take care in the medical setting to thoroughly decontaminate instruments and wash hands.

- **Pharmacologic Therapy**
  - Patients may obtain further symptomatic relief by using artificial tears and topical decongestants. If artificial tear solutions sting, recommend a preservative-free formula.

**Patient Encounter 1**

This morning, a mother brings in her 13-year-old son who has been complaining of irritation, redness, and “goop” coming out of his right eye for the past 13 hours. He woke up terrified this morning because his right eye seemed glued shut. At first, the mother was concerned because his younger sister had “pink-eye” 2 weeks ago. A warm washcloth was used to ease the eye open, and upon examination, the right eye was red and revealed a whitish discharge, whereas the left eye was just red.

**What is the probable diagnosis?**

Please differentiate between bacterial, hyperacute bacterial, viral, and allergic causes based on physical assessment.

**What organisms should be suspected, and what are reasonable treatment regimens?**

If the child would have been diagnosed with viral conjunctivitis, what nonpharmacologic measures should be employed to prevent spreading?

Patients with severe subepithelial infiltration may require a topical steroid. However, topical steroids may cause serious ocular complications, increase the period of viral shedding, and may worsen herpetic conjunctivitis, which has similar symptoms as viral conjunctivitis. Only ophthalmologists should prescribe topical steroids.

### Outcome Evaluation

- Refer patients who do not see improvement within 7 to 10 days to an ophthalmologist to rule out herpetic and other infectious processes.

### ALLERGIC CONJUNCTIVITIS

#### Etiology and Clinical Presentation

Ocular allergy is a broad term that includes several diseases with the hallmark symptom of itching, often accompanied by tearing, conjunctival swelling, photophobia, and stringy or sticky mucoid discharge. Allergic conjunctivitis affects up to 40% of patients. Seasonal ocular allergy is the most common type of allergic conjunctivitis. Often, the patient’s history is positive for atopic conditions, including allergic rhinitis, asthma, or eczema. Perennial allergic conjunctivitis has similar but less severe symptoms and may not be tied to a specific time of year. Finally, conjunctivitis medicamentosa is a drug-induced form of allergic conjunctivitis caused by overuse of topical vasoconstricting agents.

#### Pathophysiology

The conjunctiva of the eye is often the initial site of contact with an environmental allergen. Mast cell degranulation occurs, and the earliest mediator is histamine, which causes itching, redness, and swelling. Leukotrienes and prostaglandins cause cellular infiltration and increased mucus secretion along with chemosis, resulting in conjunctival vasodilation.

Treatment of ocular allergy is aimed at slowing or stopping these processes. Antihistamines block the histamine receptors, prevent histamine release from the mast cells and stop eosinophil activity. Mast cell stabilizers inhibit the degranulation of mast cells, preventing mediator release. Some topical agents have multiple mechanisms of action, combining antihistaminic, mast cell stabilization, and anti-inflammatory properties (Tables 62–4, 62–5, and 62–6).

#### Treatment

- **Desired Outcomes**
  - Relief of current allergic symptoms
  - Prevention of future allergic symptoms
  - No adverse effects from treatment

- **Nonpharmacologic Therapy**
  - The primary treatment for ocular allergy is removal and avoidance of the allergen. For conjunctivitis medicamentosa, discontinue the offending medication. Apply cold compresses several times daily to reduce redness and itching and to provide symptomatic relief.

- **Pharmacologic Therapy**
  - Use a step-care approach for the treatment of allergic conjunctivitis.

    - **Step 1:** Nonmedicated, artificial tears solution. The solution dilutes or removes the allergen, providing relief while lubricating the eye. Solutions are applied two to four times daily as needed. Ointments may be used in the evenings to further moisturize the surface of the eye.Preservative-free formulations may be tried if other products sting or burn.

    - **Step 2:** Topical antihistamine or antihistamine/decongestant combination. The antihistamine/decongestant combination is more effective than either agent alone. Decongestants are vasoconstrictors that reduce redness and seem to have a small synergistic effect with the antihistamine. The only topical decongestant used in combination products is naphazoline. Topical decongestants burn and sting on instillation and commonly cause mydriasis, especially in patients with lighter-colored eyes. Topical decongestant use should be limited to less than 10 days to avoid rebound congestion.

    - **Step 3:** A mast cell stabilizer or a multiple-action agent. Use mast cell stabilizers prophylactically throughout the allergy season. Full response may take 4 to 6 weeks.

    - **Step 4:** Short-term topical corticosteroids and immunotherapy.

Alomide (loodoxamide tromethamine) solution/drops 0.1%. Fort Worth(TX): Alcon Laboratories, Inc., 2003.

Topical antihistamines are recommended before oral agents in step therapy due to the increased risk of systemic side effects with oral drugs. Topical antihistamines provide faster relief of ocular symptoms. Topical ketorolac tromethamine is approved for ocular itching.9

Outcome Evaluation

Monitor patients for relief of symptoms. Ensure an adequate trial of each agent. Refer severe cases that do not respond to an ophthalmologist.

BACTERIAL KERATITIS

Epidemiology

Thirty thousand cases of microbial keratitis occur annually in the United States.10 Microbial keratitis encompasses bacterial, fungal, and Acanthamoeba keratitis.10 Only bacterial keratitis, the most common form, is discussed here.
Pathophysiology
Bacterial keratitis is a broad term for a bacterial infection of the cornea, including corneal ulcers and corneal abscesses. The cornea in a healthy eye has natural resistance to infection, making bacterial keratitis rare. However, many factors may predispose a patient to bacterial infection by compromising the defense mechanisms of the eye (see Table 62–6). The most common pathogens in bacterial keratitis are Pseudomonas (including Pseudomonas aeruginosa) and other gram-negative rods, Staphylococci, and Streptococci. If the keratitis is related to the use of contacts, Pseudomonas and Serratia marcescens are the most common pathogens. Untreated bacterial keratitis is associated with corneal scarring and potential loss of vision. Corneal perforation may occur, and the patient may lose the eye. In virulent organisms, this destruction may occur within 24 hours. Central corneal scarring may result in vision loss even after successful eradication of the organism.

Treatment
▶ Desired Outcomes
- Resolution of infection and corneal inflammation
- Reduced corneal pain
- Restored corneal integrity with minimal scarring
- Restored visual function

▶ General Approach to Treatment
- All cases of suspected bacterial keratitis require prompt ophthalmology consultation to prevent permanent vision loss.

▶ Pharmacologic Therapy
- Drug Choice
  - Start topical broad-spectrum antibiotics empirically. Use a loading dose for severe keratitis (Table 62–7).
  - Single-drug therapy with a fluoroquinolone is as effective as combination therapy. Resistance is seen with some fluoroquinolones, choose moxifloxacin or gatifloxacin in severe keratitis cases.
  - Fortified antibiotic therapy is an option for severe or unresponsive infections but may increase toxicity to the cornea and surrounding tissues. Fortified antibiotics are compounded products that are a higher concentration than the commercially available formulation.
- Topical corticosteroids are employed in some cases of bacterial keratitis. The suppression of inflammation may reduce corneal scarring. However, local immunosuppression, increased ocular pressure, and reappearance of the infection are disadvantages to their use. There is no conclusive evidence that they alter clinical outcomes. If the patient is already on topical corticosteroids when the keratitis occurs, discontinue use until the infection is eliminated.
- Outcome Evaluation
  - Symptomatic improvement is indicative of therapeutic efficacy.
  - Adjust treatment based on culture and sensitivity reports.

</tr>
</tbody>
</table>

*Use for resistant Enterococcus and Staphylococcus species and penicillin allergy. Due to the absence of gram-negative activity, do not use vancomycin or bacitracin for single-agent empiric therapy in bacterial keratitis.*

Normal Vision

- Modify the treatment regimen if the patient does not show improvement within 48 hours.
- Gram-negative keratitis will have increased inflammation in the first 24 to 48 hours, even on appropriate therapy.
- Taper therapy based on clinical response.
- Reculture if negative clinical response; discontinue antibiotics 12 to 24 hours before culturing for best results.
- Contact lenses wearers should be educated about the increased risk of infection overnight and continuous wear and the importance of adherence to contact lens hygiene.

MACULAR DEGENERATION

Epidemiology and Etiology

Age-related macular degeneration (AMD) is the primary cause of severe, irreversible vision impairment in developed countries (Figures 62–2 and 62–3). The prevalence increases with age.\(^\text{11}\)

In the United States, 1.75 million people age 40 or older have advanced AMD, and another 7 million people may have intermediate AMD.\(^\text{11}\) It is projected that almost 3 million people will develop AMD by 2020.\(^\text{12}\) The causes of AMD are not completely known (Table 62–8).\(^\text{11}\)

Pathophysiology

AMD is a deterioration of the macula, the central portion of the retina. The macula facilitates central vision and high-resolution visual acuity because it has the highest concentration of photoreceptors in the retina. The loss of central vision leads to irreversible loss of the ability to drive, read, and perform other fine visual tasks like recognize faces.\(^\text{13}\) Peripheral vision is preserved, allowing mobility.\(^\text{11}\) AMD is characterized by one or more of the following: drusen formation, retinal pigment abnormalities (eg, hypo- or hyperpigmentation), geographic atrophy, and neovascular maculopathy.\(^\text{11}\)

| Table 62–8 Risk Factors for AMD |
|------------------------------|-------------------|
| **Definite Risk Factors**    | **Potential Risk Factors** |
| Advancing age                | Cardiovascular disease |
| Light pigmentation (white   | Hypertension |
| ethnicity)                   | Low dietary intake of |
| Cigarette smoking           | antioxidant vitamins or zinc |
| Family history              | Increased body mass index |
|                             | Higher dietary fat intake |

Clinical Presentation and Diagnosis of AMD\(^\text{12,14}\)

Symptoms
- Mild blurry central vision
- Difficulty reading
- Trouble with color and contrast
- Painless, progressive, blurring of central vision
- Sudden loss or distortion of vision possible

Signs
- Drusen
- Retinal pigment epithelial mottling

Other Diagnostic Tests
- Amsler grid abnormalities indicate fluid in subretinal space (see Figures 62–4 and 62–5)
- Dilated fundus examination shows drusen and pigmentary abnormalities in the macula
- Rapid sequence fluorescein angiography shows leakage in the neovascular form

Age-related macular degeneration

FIGURE 62–3. The scene in Figure 62–2 as it might be viewed by a person with age-related macular degeneration. (From the National Eye Institute, National Institutes of Health Ref. No. EDS05. http://www.nei.nih.gov/photo/)
Based on clinical presentation, AMD is classified as early, intermediate, or advanced. Early AMD is characterized by small or intermediate drusen and minimal macular pigment abnormalities. These patients generally have normal central vision. Intermediate AMD patients have medium or large drusen in one or both eyes.

Advanced AMD is classified as non-neovascular (also called the atrophic, nonexudative, or dry form) or neovascular (the exudative or wet form). In the non-neovascular form, the retina and other layers atrophy. In the neovascular form, new blood vessels appear. Generally, vision is already affected when patients progress to advanced AMD; vision loss is seen in both forms. Around 10% to 20% patients with the non-neovascular form will progress to the neovascular form.

**Treatment**

► **Desired Outcomes**

The primary goal of treatment for AMD is to slow the disease progression. This includes slowing the loss of visual acuity and the progression to legal blindness, along with maintaining contrast sensitivity. The secondary goals are maintaining quality of life and minimizing the adverse effects of treatment.

► **General Approach to Treatment**

**KEY CONCEPT** There is no cure for AMD, and the efficacy of most treatments is low. Newer drug developments show promise, but no treatment can reverse damage that has already occurred. Early diagnosis is critical. High-risk patients need periodic eye examinations because some patients do not notice any changes, even when neovascularization has occurred.

► **Nonpharmacologic Therapy**

- **Non-neovascular AMD** Advise patients to stop smoking, as observational data supports a causal relationship between smoking and AMD.

  Drusen ablation by laser has been used however; it is not clear whether the treatment reduces progression to neovascular AMD. Treatments may induce neovascularization and retinal atrophy. Other nonpharmacologic therapies are in trials, but there is insufficient evidence for experts to recommend these procedures at this time.

- **Neovascular AMD** Thermal laser photocoagulation reduces severe visual loss 2 to 5 years after the procedure, but leads to an immediate and permanent reduction in central vision. There is a 50% chance that leakage will recur in the next 2 years after the procedure.

- **Use of photodynamic therapy in combination with the medication verteporfin has shown success in clinical trials. Verteporfin is reconstituted to achieve the desired dose of 6 mg/m² body surface area and diluted with 5% dextrose for injection to a total infusion volume of 30 mL. The drug is given intravenously, and laser light delivery is performed on the patient 15 minutes after the start of the 10-minute infusion with verteporfin. Photodynamic therapy uses nonthermal red light to activate verteporfin, which produces reactive oxygen species that locally damage the neovascular endothelium. Verteporfin treatment reduces the risk of loss of visual acuity and legal blindness over 1 to 2 years. Long-term results are not yet available. Severe photosensitivity for 3 to 5 days after the procedure is common, and some patients experience a severe loss of vision. Eventually, most patients have some visual recovery. This procedure requires multiple treatments over time.

- **Pharmacologic Therapy**

  There are no approved pharmacologic treatments for non-neovascular AMD. The Age-Related Eye Disease Study showed that a supplement containing ascorbic acid 500 mg, vitamin E 400 IU, β-carotene 15 mg, zinc oxide 80 mg, and cupric oxide 2 mg reduced the rate of clinical progression of all types of AMD by 28% in patients with at least intermediate macular degeneration. No benefit was seen in patients with earlier stages of AMD; however, the duration of the study may have been insufficient to detect this benefit. Currently, experts recommend antioxidant supplementation for intermediate AMD or advanced AMD in one eye. Supplementation is not without risk. For example, β-carotene supplementation in smokers may increase the risk of developing lung cancer. At this time, it is not clear from the evidence whether a patient is at a high risk but without symptoms of AMD would benefit from supplementation.

  Vascular endothelial growth factor induces angiogenesis, increases vascular permeability, and increases inflammation, all of which are thought to contribute to neovascular AMD. Pegaptanib, a vascular endothelial growth factor antagonist, binds to these growth factors in an attempt to suppress neovascularization. In clinical studies, patients treated with pegaptanib experienced a slower rate of visual decline than patients treated with a placebo injection. Vision loss continued to occur in patients, and the drug was less effective in the second year of treatment. Ranibizumab, binds to and inhibits the activity of vascular endothelial growth factor (VEGF) A, a critical protein in angiogenesis. In one clinical study, 95% of patients treated with ranibizumab maintained visual acuity after 12 months compared with 62% of control patients. Aflibercept, a VEGF-A inhibitor was approved for wet age-related macular degeneration. The dosing of 2 mg every 4 weeks for the first 3 months, followed by 2 mg every 8 weeks thereafter, results in seven injections during the first year of treatment compared with 12 injections with other products. Patients treated with aflibercept or other VEGF-A inhibitors are at risk for arterial thrombotic events. Specifically, stroke, nonfatal heart
Patient Encounter 3, Part 2

After meeting with a retinologist, JJ has been diagnosed with early non-neovascular age-related macular degeneration. He has been advised to use a magnifying glass for his left eye instead of closing it while reading. He has been advised to only drive during the day.

What pharmacologic and nonpharmacologic treatment options are available for JJ?

JJ’s daughter is very frustrated that her dad is not on a “medication,” as a family friend is being treated for macular degeneration. What information is necessary to relay to JJ’s daughter?

What monitoring is appropriate for JJ?

JJ’s daughter is concerned that she will develop macular degeneration because she read that it runs in families. What symptoms should JJ’s daughter watch for as she gets older?

FIGURE 62–4. Amsler grid distortions in the lines of the grid may be caused by subtle changes in central vision due to fluid in the subretinal space. This is the Amsler grid as it appears to someone with normal vision. (From the National Eye Institute, National Institutes of Health Ref. No. EC03. http://www.nei.nih.gov/photo/)

FIGURE 62–5. Amsler grid as it might appear to someone with AMD. (From the National Eye Institute, National Institutes of Health Ref. No. EC04. http://www.nei.nih.gov/photo/)

Outcome Evaluation

Monitor patients for acute and chronic vision changes or loss. The Amsler grid (Figures 62–4 and 62–5) and frequent eye examinations may detect changes more quickly. The long-term prognosis for AMD is poor; therefore, it is important to work with patients and families as vision decreases. Monitor patients for inability to drive and remove driving privileges as appropriate.

DRY EYE

Epidemiology and Etiology

Dry eye is a frequent cause of eye irritation. The lack of a single diagnostic test for the condition limits the available epidemiologic data. Reports of the prevalence of dry eye range from 5% to 30%, being more frequent in elderly patients. The risk factors for dry eye are listed in Table 62–9. The use of caffeine is associated with a decreased risk of dry eye. Dry eye that is left untreated

Clinical Presentation and Diagnosis of Dry Eye

**General**

Many other ocular diseases have similar symptoms. Patients with suggestive symptoms without signs should be placed on a treatment trial. Repeated observations may be required for a clinical diagnosis.

**Symptoms**
- Dry or foreign body sensation
- Mild itching
- Burning or stinging
- Photophobia
- Ocular irritation or soreness
- Blurry vision
- Contact lens intolerance
- Diurnal fluctuation or symptoms worsening later in the day

**Signs**
- Redness
- Mucous discharge
- Increased blink frequency
- Tearing

**Other Diagnostic Tests**
- The tear break-up time test assesses the stability of precorneal tear film. Break-up times of less than 10 seconds are considered abnormal.
- Ocular surface dye staining assesses the ocular surface and will show blotchy areas in the dry eye.
- Schirmer test evaluates aqueous tear production but is not diagnostic. Results of 5 mm or less are considered abnormal.
- Assess corneal sensation if trigeminal nerve dysfunction is suspected.
- Consider an autoimmune disorder if significant dry eyes, other signs and symptoms, or family history are present.

Pathophysiology

The surface of the eye and the tear-secreting glands work together as an integrated unit that refreshes the tear supply and clears away used tears. Dry eye may be caused by impaired tear secretion and/or increased tear evaporation. It has been suggested that dry eye be called “dysfunctional tear syndrome,” as all the predisposing factors cause some disruption of the tear. Dysfunctional tear film may result in an inflammatory response on the ocular surface called keratoconjunctivitis sicca.
